This textbook is dedicated to the patients we serve and the healthcare professionals, trainees, and students learning the art of surgery. We are grateful to our families and friends for their support in completing this project.

CONTRIBUTORS

Mohammad Abbass, MD
Northwestern University Feinberg School of Medicine
Chicago, Illinois

Fariba Abbassi, MD
Research Fellow
Department of Abdominal Surgery and Transplantation
University Hospital Zurich;
Research Fellow
Epidemiology, Biostatistics and Prevention Institute
University of Zurich
Zurich, Switzerland

Abdurrahman T. Abdelzaher, MD
Surgical Oncology Postdoctoral Research Fellow
Surgery
Alvin J. Siteman Comprehensive Cancer Center at Washington University School of Medicine, Department of Surgery, Section of Surgical Oncology
St. Louis, Missouri

Rachael C. Acker, MD
General Surgery Resident
Department of Surgery
University of Pennsylvania
Philadelphia, Pennsylvania

Andrew Adams, MD, PhD
Professor
Department of Surgery
University of Minnesota
Minneapolis, Minnesota

Reid B. Adams, MD
Claude A Jessup Professor
Department of Surgery
University of Virginia School of Medicine;
Chief Medical Officer
University of Virginia
Charlottesville, Virginia

Divyansh Agarwal, MD, PhD
Clinical Fellow in Surgery
Harvard Medical School
Massachusetts General Hospital
Boston, Massachusetts

Alexandra Z. Agathis, MD
Resident
Department of Surgery
Icahn School of Medicine at Mount Sinai
New York, New York

Vanita Ahuja, MD, MPH, MBA
Associate Chief of Staff - Education
Minneapolis Veterans Affairs Healthcare System
Minneapolis, Minnesota

Yewande Alimi, MD, MHS
Assistant Professor of Surgery
Surgery
Georgetown University School of Medicine
Washington, District of Columbia

John C. Alverdy, MD, FACS, FSIS
Sara and Harold Lincoln Thompson Professor of Surgery, Executive Vice Chair
Department of Surgery
Pritzker School of Medicine
University of Chicago
Chicago, Illinois

Seema Anandalwar, MD, MPH
Clinical Instructor in Surgery
Surgery
R Adams Cowley Shock Trauma Center
Baltimore, Maryland

Peter Angelos, MD, PhD, FACS, MAMSE, HEC-C
Linda Kohler Anderson Professor of Surgery and Surgical Ethics
Department of Surgery
Chief, Endocrine Surgery
Director, MacLean Center for Clinical Medical Ethics
University of Chicago
Chicago, Illinois

Mark Antkowiak, MD
Resident Physician
Department of Surgery
University of California San Diego
San Diego, California

Imran J. Anwar, MD
General Surgery Resident
Department of Surgery
Duke University
Durham, North Carolina

Rachel D. Appelbaum, MD, FACS
Assistant Professor
Department of Surgery
Vanderbilt University Medical Center
Nashville, Tennessee

Shipra Arya, MD, SM
Professor
Department of Surgery
Stanford University School of Medicine
Stanford, California

Anthony Atala, MD
Director
Wake Forest Institute for Regenerative Medicine
William H. Boyce Professor and Chair
Department of Urology
Wake Forest School of Medicine
Winston-Salem, North Carolina

Andrew Nagy Atia, MD, MBA
Department of Surgery
Division of Plastic, Maxillofacial, and Oral Surgery
Duke University Hospital
Durham, North Carolina

Jason M. Aubrey, MD
Surgical Resident
General Surgery
Corewell Health - Michigan State University
Grand Rapids, Michigan

Mary T. Austin, MD, MPH
Professor
Surgical Oncology
University of Texas MD Anderson Cancer Center
Houston, Texas

Reed I. Ayabe, MD
Assistant Professor of Surgery
Department of Surgery
University of California Irvine
Irvine, California

Hassan Aziz, MD, FACS
Assistant Professor of Surgery
Department of Surgery
University of Iowa
Iowa City, Iowa

Idelberto Raul Badell, MD
Associate Professor
Department of Surgery
Emory University School of Medicine
Atlanta, Georgia

Andrew Patrick Bain, MD
Surgery Resident
Department of Surgery
UT Southwestern Medical Center
Dallas, Texas

Aditi Balakrishna, MD
Assistant Professor
Anesthesiology, Division of Critical Care
Vanderbilt University Medical Center
Nashville, Tennessee

Elise Bardawil, MD
Assistant Professor Division of Minimally Invasive Gynecologic Surgery
Obstetrics and Gynecology
Washington University in St. Louis
St. Louis, Missouri

Edward M. Barksdale, Jr., MD
Department of Orthopaedic Surgery
Washington University School of Medicine
St. Louis, Missouri

Georgia Beasley, MD, MHSc
Associate Professor of Surgery With Tenure
Department of Surgery
Duke University
Durham, North Carolina

Igor Belyansky, MD
Chief of General Surgery
Director of Abdominal Wall Reconstruction Program
General Surgery
Anne Arundel Medical Center
Annapolis, Maryland

Cherisse Berry, MD, FACS
Professor of Surgery
Vice Chair of Academic Affairs, Department of Surgery
Rutgers Health, New Jersey School of Medicine
Newark, New Jersey

Tina Bharani, MD
Fellow
Department of Surgery
University of Iowa Hospitals and Clinics
Iowa City, Iowa

Vijay Bhoj, MD, PhD
Assistant Professor
Department of Pathology and Laboratory Medicine
University of Pennsylvania
Philadelphia, Pennsylvania

Monica Bhutiani, MD, MEd
Assistant Professor
Anesthesiology
Vanderbilt University Medical Center
Nashville, Tennessee

Letitia Bible, MD, FACS
Assistant Professor
Trauma and Acute Care Surgery
University of Florida
Gainesville, Florida

Karl Y. Bilimoria, MD, MS
Director of Surgical Outcomes and Quality Improvement Center (SOQIC)
Chair, Department of Surgery
Indiana University
Indianapolis, Indiana

Dan Blazer III, MD, FACS
Professor of Surgery
Department of Surgery
Duke University
Durham, North Carolina

Joshua I.S. Bleier, MD, FACS, FASCRS
Professor of Clinical Surgery
Department of Surgery
University of Pennsylvania, Perelman School of Medicine
Philadelphia, Pennsylvania

Rachel Bluebond-Langner, MD
Associate Professor
Department of Plastic Surgery
New York University Langone Health
New York, New York

Mary E. Bokenkamp, MD
Chief Resident
Department of Surgery
Dell Medical School at the University of Texas at Austin
Austin, Texas

Genevieve Boland, MD, PhD
Vice Chair of Research
Department of Surgery
Massachusetts General Hospital
Boston, Massachusetts

Brian A. Boone, MD
Associate Professor
Department of Surgery, Division of Surgical Oncology
West Virginia University
Morgantown, West Virginia

Edmond W. Box III, MD
T32 Surgical Oncology Research Fellow
Department of Surgery
University of Miami
Miami, Florida

Ludwik Krzysztof Branski, MD, MMS
Associate Professor of Surgery
Department of Surgery
University of Texas Medical Branch;
Staff Surgeon
Shriners Hospital for Children
Galveston, Texas

Benjamin N. Breyer, MD, MAS
Chair, Department of Urology
Professor of Urology
University of California, San Francisco
San Francisco, California

Meaghan Broderick, MD
Instructor
Surgical Critical Care and Acute Care Surgery
R Adams Cowley Shock Trauma Center
Baltimore, Maryland

Ryan C. Broderick, MD
Associate Professor
Department of Surgery, Division of Minimally Invasive Surgery
University of California San Diego
La Jolla, California

Benjamin Sands Brooke, MD, PhD, FACS, DFSVS
Professor
Chief, Division of Vascular Surgery
Department of Surgery
Adjunct Professor
Department of Population Health Sciences
University of Utah
Salt Lake City, Utah

Carlos V.R. Brown, MD
Chief, Division of Acute Care Surgery
Department of Surgery
Dell Medical School at the University of Texas at Austin
Austin, Texas

Paul R. Burchard, MD
Resident
General Surgery
University of Rochester Medical Center
Rochester, New York

Clay Cothren Burlew, MD
Professor of Surgery
Department of Surgery
University of Colorado Anschutz Medical Campus
Aurora, Colorado

Ruth L. Bush, MD, JD, MPH
Professor
Associate Dean, Educational Affairs
Professor of Surgery
Department of Surgery
John Sealy School of Medicine
University of Texas Medical Branch
Galveston, Texas

Alfredo Maximiliano Carbonell II, DO
Co-Director Hernia Center
Department of Surgery
Prisma Health – Upstate;
Professor
Department of Surgery
University of South Carolina School of Medicine, Greenville
Greenville, South Carolina

Leandro Totti Cavazzola, MD, MSc, PhD, FACS
Associate Professor
Department of Surgery
Universidade Federal do Rio Grande do Sul, Porto Alegre;
Associate Professor
Department of Surgery
Hospital de Clínicas de Porto Alegre
Rio Grande do Sul, Brazil

Paul Cederna, MD
Chief of Plastic Surgery
Department of Surgery
University of Michigan
Ann Arbor, Michigan

Hani Chanbour, MD
Resident
Neurosurgery
Vanderbilt University
Nashville, Tennessee

William C. Chapman, Sr., MD
Professor of Surgery
Department of Surgery
Washington University in St. Louis
St. Louis, Missouri

Anthony Charles, MD, MPH
Professor of Surgery
Department of Surgery
University of Vermont
Burlington, Vermont

Genevieve Chartrand, MSc, MD, FRCSC
Surgeon
Chirurgie Digestive
Centre Hospitalier de l'Université de Montréal
Montreal, Quebec, Canada

Mihir Chaudhary, MD, MPH
Surgical Fellow
Department of Surgery
Emory University
Atlanta, Georgia

Michael Lee Cheatham, MD, FACS, FCCM
Trauma Surgeon
Department of Surgical Education
Orlando Regional Medical Center
Orlando, Florida

Edward P. Chen, MD
Professor of Surgery
Department of Surgery
Duke University
Durham, North Carolina

Herbert Chen, MD
Chair and Fay Fletcher Kerner Chair
Surgery
University of Alabama at Birmingham
Surgeon-in-Chief
University of Alabama at Birmingham Health System
Senior Associate Dean
University of Alabama at Birmingham Heersink School of Medicine
Birmingham, Alabama

Karan R. Chhabra, MD, MSc
Assistant Professor
Departments of Surgery and Population Health
New York University Grossman School of Medicine;
Assistant Professor
Division of Bariatric and General Surgery
NYC Health + Hospitals/Bellevue
New York, New York

Ifeanyi David Chinedozi, MD
Surgery Resident
Department of Surgery
Johns Hopkins University
Baltimore, Maryland

Perry S. Choi, MD
Resident Physician
Department of Cardiothoracic Surgery
Stanford University
Palo Alto, California

Konstantinos Chouliaras, MD
Surgical Oncologist
Division of Surgery
Baptist MD Anderson
Jacksonville, Florida

Ngoc-Quynh Chu, MD
Clinical Fellow
Thoracic Surgery
Memorial Sloan Kettering Cancer Center
New York, New York

Yun Shin Chun, MD, FACS
Professor
Surgical Oncology
University of Texas MD Anderson Cancer Center
Houston, Texas

Dai H. Chung, MD, MBA
Professor
Strauss Endowed Chair in Pediatric Surgery
Department of Surgery
UT Southwestern Medical Center;
Chief Medical Executive
Children's Health;
Chief Medical Officer
Joint Pediatric Enterprise
Dallas, Texas

Bryan M. Clary, MD, MBA
Professor and Chair
Department of Surgery
University of California San Diego
San Diego, California

Pierre-Alain Clavien, MD, PhD
Professor and Chairman
University of Zurich
Swiss Medical Network
Zurich, Switzerland

Thomas West Clements, MD, FRCSC
Assistant Professor
Department of Surgery
The University of Texas Health Science Center at Houston
Houston, Texas

Orly M. Coblens, MD, FACS
Associate Professor
Otolaryngology - Head and Neck Surgery
University of Texas Medical Branch
Galveston, Texas

Dawn Marie Coleman, MD
Division Chief, Vascular and Endovascular Surgery
Department of Surgery
Duke University
Durham, North Carolina

Jesse A. Columbo, MD, MS
Assistant Professor of Surgery
Section of Vascular Surgery
Dartmouth Hitchcock Medical Center
Lebanon, New Hampshire

Seth J. Concors, MD
Assistant Professor
Department of Surgery
Emory University
Atlanta, Georgia

Daniel Counihan, MD, MA
House Officer
Department of Surgery
Boston Medical Center
Boston, Massachusetts

Mitchell W. Cox, MD
Chief, Division of Vascular Surgery
Professor of Surgery
Department of Surgery
University of Texas Medical Branch
Galveston, Texas

Joshua L. Crapps, MD
Resident Physician
Department of Surgery and Perioperative Care
University of Texas at Austin Dell Medical School
Austin, Texas

Joseph G. Crompton, MD, PhD
Assistant Professor
Department of Surgery
University of California, Los Angeles
Los Angeles, California

Andi Jean Cummins, MD
Resident Physician
Plastic Surgery
University of Texas Medical Branch
Galveston, Texas

Carrie Elizabeth Cunningham, MD, MPH
Associate Professor
Department of Surgery
Massachusetts General Hospital
Boston, Massachusetts

Thomas A. D'Amico, MD
Gary Hock Endowed Professor
Department of Surgery
Duke University Medical Center;
Director
Thoracic Oncology Program
Chief
General Thoracic Surgery
Duke Cancer Institute
Durham, North Carolina

Michael I. D'Angelica, MD, FACS
Enid Haupt Endowed Chair in Surgery
Department of Surgery
Memorial Sloan Kettering Cancer Center;
Professor of Surgery
Department of Surgery
Weill Cornell School of Medicine
New York, New York

Jorge Daes, MD, FACS
Director
Minimally Invasive Surgery
Clinica Bautista
Barranquilla, Atlantico, Colombia

Brian J. Daley, MD, MBA, FACS
Vice Chair
Department of Surgery
University of Tennessee Medical Center at Knoxville
Knoxville, Tennessee

Alan Dardik, MD, PhD
Professor
Surgery and Interventional Radiology
Icahn School of Medicine at Mount Sinai
New York, New York;
Emeritus Professor
Surgery and Cellular and Molecular Physiology
Yale School of Medicine
New Haven, Connecticut

Resident Physician
Department of Surgery
University of Chicago
Chicago, Illinois

Sharon Henry, MD
Professor of Trauma Surgery
Department of Surgery
University of Maryland School of Medicine;
Director of Wound Healing and Metabolism
Program in Trauma
R Adams Cowley Shock Trauma Center
Baltimore, Maryland

Fernando A. Herbella, MD
Associate Professor
Department of Surgery
Federal University of Sao Paulo
Sao Paulo, Brazil

Paul Tarver Hernandez, MD
Assistant Professor
Colorectal Surgery
Hospital of the University of Pennsylvania
Philadelphia, Pennsylvania

John Herndon, BA
Staff Scientist
Department of Surgery
Washington University School of Medicine
St. Louis, Missouri

Jill R. Higgins, ACNP
Nurse Practitioner
Cardiothoracic Surgery
University of California San Diego
San Diego, California

Robert S.D. Higgins, MD, MSHA
President and Chief Academic Officer
Rush University
Chicago, Illinois

Vanessa P. Ho, MD, PhD, MPH
Associate Professor
Surgery
MetroHealth Medical Center;
Associate Professor
Population and Quantitative Health Sciences
Case Western Reserve University School of Medicine
Cleveland, Ohio

Melissa E. Hogg, MD, MS
Division Chief, General Surgery
Clinical Professor
Department of Surgery
NorthShore
Chicago, Illinois

Julie L. Holihan, MD, MS
Assistant Professor of Surgery
Surgery
McGovern Medical School
Houston, Texas

Rachel C. Hooper, MD
Clinical Assistant Professor of Surgery
Department of Surgery
University of Michigan
Ann Arbor, Michigan

Nir Horesh, MD
Colorectal Surgeon
Colorectal Surgery
Cleveland Clinic Florida
Weston, Florida

James R. Howe V, MD
Director, Division of Surgical Oncology and Endocrine Surgery
Department of Surgery
University of Iowa Carver College of Medicine
Iowa City, Iowa

Yinin Hu, MD, FACS
Assistant Professor
Department of Surgery
University of Maryland School of Medicine
Baltimore, Maryland

Lioba Huelsboemer, MD
Postdoctoral Research Fellow
Plastic Surgery
Yale University
New Haven, Connecticut

Tasha Hughes, MD, MPH
Clinical Associate Professor
Department of Surgery
University of Michigan
Ann Arbor, Michigan

Kelly K. Hunt, MD
Professor and Chair
Breast Surgical Oncology
University of Texas MD Anderson Cancer Center
Houston, Texas

Matthew M. Hutter, MD, MBA, MPH
Professor of Surgery
Surgery
Harvard Medical School;
Director, Codman Center for Clinical Effectiveness in Surgery
Department of Surgery
Massachusetts General Hospital
Boston, Massachusetts

Michelle Huyser, MD
Surgical Oncologist
Surgery
Phoenix Indian Medical Center;
Surgical Oncologist
Surgery
Mayo Clinic Arizona
Phoenix, Arizona

Colby John Hyland, MD
Resident Physician
Surgery
Mass General Brigham
Boston, Massachusetts

Benjamin Rush Endowed Chair of Surgery
Department of Surgery
Assistant Dean of Simulation
Rutgers New Jersey Medical School;
Surgery Chief of Service
University Hospital
Newark, New Jersey

Soren Jonzzon, MD
Resident Physician
Department of Neurological Surgery
Vanderbilt University Medical Center
Nashville, Tennessee

Mary Junak, MD
General Surgery Resident
Department of Surgery
University of Wisconsin
Madison, Wisconsin

Gregory Jurkovich, MD
Distinguished Professor and Vice Chairman
Department of Surgery
University of California, Davis
Sacramento, California

Haytham M.A. Kaafarani, MD, MPH, FACS
Professor of Surgery
Surgery
Harvard Medical School;
Trauma Medical Director
Surgery
Hospital Director of Safety and Quality
Massachusetts General Hospital
Boston, Massachusetts

Puja Kachroo, MS, MD
Associate Professor of Cardiac Surgery
Department of Surgery
Washington University in St. Louis
St. Louis, Missouri

Steven Kahn, MD, FACS, FABA
Professor of Surgery, Chief of Burn Surgery
Department of Surgery
Medical University of South Carolina
Charleston, South Carolina

Kristen N. Kaiser, MD
Resident
General Surgery
Indiana University
Indianapolis, Indiana

Matthew F. Kalady, MD, FASCRS, FACS
Professor of Surgery
Department of Surgery
Director, Division of Colon and Rectal Surgery
The Ohio State University Wexner Medical Center;
Medical Director, Clinical Cancer Genetics
Director, The James Colorectal Cancer Center
Columbus, Ohio

Elishama N. Kanu, MD, MA
Resident Physician
Department of Surgery
Duke University Medical Center
Durham, North Carolina

Lillian S. Kao, MD, MBA
Professor
Department of Surgery
McGovern Medical School at the University of Texas Health Science Center at Houston
Houston, Texas

Sahil Kapur, MD
Department of Plastic and Reconstructive Surgery
University of Texas MD Anderson Cancer Center
Houston, Texas

Giorgos C. Karakousis, MD
Professor of Surgery
Department of Surgery
University of Pennsylvania
Philadelphia, Pennsylvania

Jeffrey Edward Keenan, MD
Assistant Professor
Department of Surgery
Duke University Medical Center
Durham, North Carolina

Rachel R. Kelz, MD, MSCE, MBA
William Maul Measey Professor of Surgery
Department of Surgery
University of Pennsylvania
Philadelphia, Pennsylvania

Robert Keskey, MD, PhD
Surgical Critical Care Fellow
Department of Surgery
University of Chicago
Chicago, Illinois

Dineo Khabele, MD
Professor and Chair
Obstetrics and Gynecology
Washington University School of Medicine
St. Louis, Missouri

Jina Kim, MD
Endocrine Surgeon
Department of Surgery
Inova Health System
Falls Church, Virginia

Paul Taehoon Kim, MD
General/MIS Surgeon
General Surgery
Luminis Health
Annapolis, Maryland

Elizabeth Gherardi King, MD
Assistant Professor
Division of Vascular and Endovascular Surgery
Boston University Chobanian and Avedisian School of Medicine
Boston, Massachusetts

William H. Kitchens, Jr., MD, PhD, FACS, FAST
Associate Professor
Department of Surgery
Emory University School of Medicine
Atlanta, Georgia

V. Suzanne Klimberg, MD, PhD
Professor and Courtney M Townsend, Jr, MD Distinguished Chair in General Surgery
Department of Surgery
University of Texas Medical Branch
Galveston, Texas;
Clinical Director of the University of Texas Medical Branch Cancer Center
Adjunct Professor
Department of Breast Surgical of Oncology
University of Texas MD Anderson Cancer Center
Houston, Texas

Meera Kotagal, MD, MPH
Assistant Professor
Division of Pediatric General and Thoracic Surgery
Cincinnati Children's Hospital Medical Center;
Assistant Professor
Department of Surgery
University of Cincinnati College of Medicine
Cincinnati, Ohio

Benjamin D. Kozower, MD, MPH
Professor
Department of Surgery
Washington University School of Medicine
St. Louis, Missouri

Daniel Kreisel, MD, PhD
Professor of Surgery, Pathology and Immunology,
G. Alexander Patterson MD/Mid-America Transplant Endowed Distinguished Chair in Lung Transplantation
Department of Surgery
Washington University School of Medicine
St. Louis, Missouri

Alexander Sasha Krupnick, MD
Chief of Thoracic Surgery
Department of Surgery
University of Maryland
Baltimore, Maryland

Kevin P. Labadie, MD
Complex General Surgical Oncology Fellow
Department of Surgery
City of Hope
Duarte, California

Mitchell R. Ladd, MD, PhD
Assistant Professor
General Surgery, Division of Pediatric Surgery
Assistant Professor
Wake Forest Institute for Regenerative Medicine
Assistant Professor
Biomedical Engineering
Assistant Professor
Pediatrics
Wake Forest University School of Medicine
Winston-Salem, North Carolina

Jennifer LaFemina, MD
Associate Professor
Program Director of General Surgery Residency
Department of Surgery
University of Massachusetts Chan Medical School
Worcester, Massachusetts

Sandhya A. Lagoo-Deenadayalan, MD, PhD, FACS
Professor of Surgery
Duke University
Durham, North Carolina

Geeta Lal, MD, MSc, FRCS(C), FACS
Professor
Department of Surgery, Division of Surgical Oncology and Endocrine Surgery
University of Iowa
Iowa City, Iowa

Christine L. Lau, MD, MBA
Buxton Professor and Chair
Department of Surgery
University of Maryland
Baltimore, Maryland

Jennifer Lawton, MD
Chief of Cardiac Surgery
Professor
Johns Hopkins Division of Cardiac Surgery
Baltimore, Maryland

Anson Michael Lee, MD
Assistant Professor
Cardiothoracic Surgery
Stanford University
Stanford, California

Jani J. Lee, MD, RPVI
Assistant Professor
Department of Surgery
University of Texas Medical Branch
Galveston, Texas

Jason T. Lee, MD
Chief of Vascular Surgery
Division of Vascular Surgery
Stanford University Medical Center
Palo Alto, California

Z-Hye Lee, MD
Assistant Professor
Department of Plastic Surgery
University of Texas MD Anderson Cancer Center
Houston, Texas

Joshua Leinwand, MD, MSE
Surgical Oncology Fellow
Department of Surgery
Memorial Sloan Kettering Cancer Center
New York, New York

L. Scott Levin, MD, FACS
Chairman
Orthopaedic Surgery
Professor of Surgery
Division of Plastic Surgery
University of Pennsylvania Health System
Philadelphia, Pennsylvania

Edward A. Levine, MD
Professor of Surgery
Surgery
Wake Forest University
Winston-Salem, North Carolina

Elizabeth J. Lilley, MD, MPH
Associate Surgeon
Department of Surgery, Division of Surgical Oncology
Brigham and Women's Hospital;
Associate Surgeon
Center for Sarcoma and Bone Oncology, Center for Melanoma Oncology
Affiliate Faculty
Department of Supportive Oncology
Dana-Farber Cancer Institute;
Assistant Professor
Department of Surgery
Harvard Medical School
Boston, Massachusetts

Ines C. Lin, MD, MSEd, FACS
Associate Professor
Surgery (Plastic Surgery); Orthopaedic Surgery (Secondary)
Program Director, Hand Surgery Fellowship
Orthopaedic Surgery
University of Pennsylvania
Philadelphia, Pennsylvania

Brenessa Lindeman, MD, MEHP
Associate Professor
Surgery
University of Alabama at Birmingham
Birmingham, Alabama

David C. Linehan, MD
CEO
University of Rochester Medical Center
Dean
School of Medicine and Dentistry
Senior Vice President
Health Sciences
University of Rochester
Rochester, New York

David Liska, MD, FACS, FASCRS
Chair
Colorectal Surgery, Digestive Disease Institute
Cleveland Clinic;
Associate Professor
Surgery
Cleveland Clinic Lerner College of Medicine at Case Western Reserve University
Cleveland, Ohio

Chengyang Liu, MD
Perelman School of Medicine
University of Pennsylvania
Philadelphia, Pennsylvania

Mengyuan Liu, MD
Assistant Attending
Department of Surgery
Memorial Sloan Kettering Cancer Center
New York, New York

Olle Ljungqvist, MD PhD
Professor Emeritus Surgery
Department of Surgery
School of Medical Sciences
Örebro University
Örebro, Sweden;
Professor Emeritus Surgery, Metabolism, and Nutrition
Molecular Medicine and Surgery
Karolinska Institutet
Stockholm, Sweden

Jayme E. Locke, MD, MPH
Vice President of Medical Development for Xenotransplantation
United Therapeutics
Adjunct Professor of Surgery
NYU Langone Health
New York, New York

Sarah Loh, MS, MD
Physician
Vascular Surgery
Yale New Haven Hospital
New Haven, Connecticut

David J. Lourié, MD, FACS
Director
Minimally Invasive Surgery
Huntington Hospital
Pasadena, California

Lea Lowenfeld, MD
Assistant Professor
Department of Surgery
Weill Cornell Medicine - New York Presbyterian Hospital
New York, New York

Richard Lu, MD, FACS
Associate Professor
Department of Surgery
University of Texas Medical Branch
Galveston, Texas

Heather G. Lyu, MD, MBI
Assistant Professor
Surgical Oncology
University of Texas MD Anderson Cancer Center
Houston, Texas

Michael M. Madani, MD
Professor and Chief
Cardiovascular and Thoracic Surgery
UC San Diego School of Medicine
La Jolla, California

David A. "Sasha" Mahvi, MD
Assistant Professor of Surgery
Beth Israel Deaconess Medical Center
Boston, Massachusetts

David M. Mahvi, MD
Distinguished University Professor, Department of Surgery
Medical University of South Carolina
Charleston, South Carolina

Amelia W. Maiga, MD, MPH
Assistant Professor of Surgery
Department of Surgery
Vanderbilt University Medical Center
Nashville, Tennessee

Mahmoud B. Malas, MD, MHS, RPVI, FACS
Professor of Surgery
Chief, Division of Vascular and Endovascular Surgery
Vice Chair of Surgery for Research
University of California San Diego
La Jolla, California;
Professor of Epidemiology
Johns Hopkins Bloomberg School of Public Health
Baltimore, Maryland

Flavio Malcher, MD, MSc
System Chief
Abdominal Core Health
Northwell Health
New York, New York;
Associate Professor
Donald and Barbara Zucker School of Medicine at Hofstra/Northwell
Hempstead, New York

James F. Markmann, MD, PhD
Vice President, Penn Transplant Institute
Vice Chair Transplant, Department of Surgery
William Maul Measey Professor in Surgical Research
University of Pennsylvania School of Medicine
Philadelphia, Pennsylvania;
Claude E. Welch Professor Emeritus
Harvard Medical School
Boston, Massachusetts

Colin Martin, MD
Professor of Surgery
Department of Surgery
Washington University in St. Louis
St. Louis, Missouri

Niels Douglas Martin, MD
Associate Professor
Department of Surgery
University of Pennsylvania
Philadelphia, Pennsylvania

Meredith C. Mason, MD
Assistant Professor
Department of Surgery
Emory University School of Medicine
Atlanta, Georgia

Sergio Mazzola Poli de Figueredo, MD
Assistant Professor
Department of Surgery
The University of North Carolina at Chapel Hill
Chapel Hill, North Carolina

Katharine L. McGinigle, MD, MPH
Associate Professor
Department of Surgery
The University of North Carolina at Chapel Hill
Chapel Hill, North Carolina

C. Lindsay McKnight, MD, FACS, CNSC
Associate Professor
Surgical Critical Care Fellowship Program Director
General Surgery Residency Associate Program Director
Department of Surgery
University of Tennessee Graduate School of Medicine
Knoxville, Tennessee

Kelly McMasters, MD, PhD
Ben A. Reid, Sr., MD Professor and Chair
The Hiram C. Polk, Jr., MD Department of Surgery
University of Louisville School of Medicine
Louisville, Kentucky

Robert Alexander Meguid, MD, MPH, FACS
Professor of Surgery
Department of Surgery
University of Colorado School of Medicine
Aurora, Colorado

John D. Mellinger, MD, FACS
Vice President
Executive
American Board of Surgery
Philadelphia, Pennsylvania;
Professor Emeritus
Department of Surgery
Southern Illinois University School of Medicine
Springfield, Illinois

Laleh G. Melstrom, MD, MSCI
Associate Professor and Chief of Surgical Oncology
Department of Surgery
City of Hope National Medical Center
Duarte, California

Nipun B. Merchant, MD
Professor of Surgery
Department of Surgery
University of Miami
Associate Director of Translational Research
Sylvester Comprehensive Cancer Center
Miami, Florida

Ryan Merkow, MD, MS
Associate Professor of Surgery
Department of Surgery
University of Chicago
Chicago, Illinois

Carmelo A. Milano, MD
Professor of Surgery
Cardiothoracic Surgery
Duke University Medical Center
Durham, North Carolina

Anna Miller, MD, FACS
Jerome J. Gilden Distinguished Professor and Vice Chair of Faculty Affairs
Orthopaedic Surgery
Washington University in St. Louis
St. Louis, Missouri

John Miura, MD
Assistant Professor of Surgery
Department of Surgery
University of Pennsylvania
Philadelphia, Pennsylvania

Jennifer M. Moffett, MD, MS, FACS
Assistant Professor
Department of Surgery
University of Texas Medical Branch
Galveston, Texas

Alicia Mohr, MD, FACS, FCCM
Professor of Surgery
Department of Surgery
University of Florida
Gainesville, Florida

Daniela Molena, MD
Surgical Director of Esophageal Cancer Surgery Program
Thoracic Surgery
Memorial Sloan Kettering Cancer Center
New York, New York

Chioma Moneme, MD, MBA
Resident
Department of Surgery
University of Virginia
Charlottesville, North Carolina

Jadie Yoonjoo Moon, BA
PhD Candidate
Graduate Program in Immunology
University of Michigan
Ann Arbor, Michigan

Marc R. Moon, MD
Denton A. Cooley, MD Chair in Cardiac Surgery
Division of Cardiothoracic Surgery
Michael E. DeBakey Department of Surgery
Baylor College of Medicine
Houston, Texas

Dimitrios Moris, MD, MSc, PhD
Surgeon
Department of Surgery
Duke University
Durham, North Carolina

David John Morrell, MD
Staff Surgeon
Surgery
Intermountain Health;
Adjunct Assistant Professor
Department of Surgery
University of Utah School of Medicine
Salt Lake City, Utah

Blake E. Murphy, MD
Vascular Surgical Resident
Division of Vascular Surgery
University of Washington
Seattle, Washington

Gary W. Nace, MD
Associate Professor
Division of Pediatric General, Thoracic, and Fetal Surgery
Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Bindi Naik-Mathuria, MD, MPH
Professor of Pediatric Surgery
Department of Surgery
University of Texas Medical Branch
Galveston, Texas

Ali Naji, MD, PhD
Professor of Surgery
Department of Surgery
University of Pennsylvania
Philadelphia, Pennsylvania

Tsukasa Nakamura, MD, PhD
Assistant Professor
Division of Transplant Surgery
the University of Arkansas for Medical Sciences
Little Rock, Arkansas

Michael L. Nance, MD
Chief, Division of Pediatric General, Thoracic, and Fetal Surgery
Department of Surgery
Children's Hospital of Philadelphia;
John M. Templeton Professor
Department of Surgery
Perelman School of Medicine at the University of Pennsylvania
Philadelphia, Pennsylvania

Matthew A. Nehs, MD
Associate Professor of Surgery
Department of Surgery
Brigham and Women's Hospital/Harvard Medical School
Boston, Massachusetts

Gregg Nelson, MD, PhD, FRCSC
Professor
Oncology
University of Calgary
Calgary, Alberta, Canada

Tim Nelson, MD
Chair
Department of Surgery
University of Oklahoma School of Community Medicine
Tulsa, Oklahoma

Hiroko Nemoto, MD, PhD
Visiting Scholar
Cardiovascular and Thoracic Surgery
University of California San Diego
La Jolla, California;
Scholar
Surgery
Yokohama City University
Yokohama, Japan

Yuri Novitsky, MD
Professor of Surgery
Department of Surgery
Columbia University Medical Center
New York, New York

Devin O'Brien Coon, MD, MSE
Associate Professor
Surgery
Harvard Medical School/Mass General Brigham
Boston, Massachusetts

Neil O'Kelly, MD
Microsurgery Fellow
Plastic Surgery
Johns Hopkins
Baltimore, Maryland

Kathleen O'Neill, MD, MSTR
Assistant Professor
Obstetrics and Gynecology
University of Pennsylvania
Philadelphia, Pennsylvania

Mitchel R. Obey, MD
Assistant Professor
Orthopaedic Surgery
Washington University in St. Louis
St. Louis, Missouri

Jon S. Odorico, MD
Professor of Surgery
Department of Surgery, Division of Transplantation
University of Wisconsin-Madison School of Medicine and Public Health;
Director, Pancreas and Islet Transplantation
Director, UW Islet Core
Surgery
University of Wisconsin Health Transplant Center
Madison, Wisconsin

John A. Olson, Jr., MD, PhD
William K. Bixby Professor and Chairman
Department of Surgery
Washington University School of Medicine;
Surgeon-in-Chief
Barnes-Jewish Hospital
St. Louis, Missouri

Franklin Olumba, MD, MPHS
Research Fellow
Department of Surgery
Washington University School of Medicine
St. Louis, Missouri

Philip Omotosho, MD
Jack Fraser Smith Professor of Surgery
Chief, Division of Minimally Invasive and Bariatric Surgery
Vice Chair, Quality and Clinical Effectiveness
Department of Surgery
Rush University
Chicago, Illinois

Mark W. Onaitis, MD
Professor of Surgery
Department of Surgery
University of California San Diego
San Diego, California

Theodore N. Pappas, MD
Professor
Department of Surgery
Duke University
Durham, North Carolina

Chetan Pasrija, MD
Johns Hopkins Hospital
Baltimore, Maryland

Hiren V. Patel, MD, PhD
Assistant Professor
Department of Urology
The Ohio State University Wexner Medical Center
Columbus, Ohio

Mayur B. Patel, MD, MPH
Chief and Professor
Division of Acute Care Surgery, Vanderbilt Department of Surgery, Section of Surgical Sciences
Vanderbilt University Medical Center
Nashville, Tennessee

Rohini Patel, MD, MPH
Resident Physician
Department of Surgery
University of California San Diego
La Jolla, California

Shalin S. Patel, MD
Assistant Professor
Orthopaedic Oncology
University of Texas MD Anderson Cancer Center
Houston, Texas

Marco G. Patti, MD
Professor
Department of Surgery
University of Virginia
Charlottesville, Virginia

Alexander Perez, MD, MSHCT, FACS
Professor of Surgery
Assistant Dean, Vice Chair, and Director for Surgical Simulation
Micheal E. DeBakey Department of Surgery
Baylor College of Medicine
Houston, Texas

Ashley A. Peters, MD, MS
Resident Physician
Department of Surgery
Loyola University Medical Center
Maywood, Illinois

Linda G. Phillips, MD, FACS
Truman G. Blocker Distinguished Professor
Chief, Division of Plastic Surgery
Department of Surgery
University of Texas Medical Branch
Galveston, Texas

Roy Phitayakorn, MD, MHPE, MAMSE, FACS
Vice Chair of Education
General and Endocrine Surgery
Massachusetts General Hospital;
Chair of Surgery Education Committee
Surgery
Harvard Medical School
Boston, Massachusetts

Iraklis I. Pipinos, MD, PhD
Professor
Department of Surgery
University of Nebraska Medical Center;
Chief
Vascular Surgery
VA Nebraska and Western Iowa Medical Center
Omaha, Nebraska

Dina Podolsky, MD
Assistant Professor of Surgery
Department of Surgery
Columbia University Medical Center
New York, New York

Bohdan Pomahac, MD
Chief
Reconstructive and Plastic Surgery
Yale School of Medicine
New Haven, Connecticut

Benjamin K. Poulose, MD, MPH
Robert M. Zollinger Lecrone-Baxter Chair
Department of Surgery
Co-Director, Center for Abdominal Core Health
The Ohio State University Wexner Medical Center
Columbus, Ohio

Alykhan M. Premji, MD
Resident Physician
Department of Surgery
University of California, Los Angeles
Los Angeles, California

Aurora D. Pryor, MD, MBA
J Murray Beardsley Professor and Chair
Department of Surgery
Warren Alpert School of Medicine, Brown University;
Surgeon-in-Chief
Department of Surgery
Brown Health
Providence, Rhode Island

Carla M. Pugh, MD, PhD
Thomas Krummel Professor of Surgery
Department of Surgery
Stanford Medicine
Stanford, California

Milo A. Puhan, MD, PhD
Professor
Epidemiology
University of Zurich;
President
Swiss School of Public Health
Zurich, Switzerland

Gretchen Purcell Jackson, MD, PhD, FACS, FACMI, FAMIA
Associate Professor, Vanderbilt University Medical Center
Vice President, Scientific Medical Officer, Intuitive Surgical
Nashville, Tennessee

Andrea L. Pusic, MD
Chief
Plastic and Reconstructive Surgery
Brigham and Women's Hospital
Boston, Massachusetts

Muhammad Umaid Rabbani, MD, FACS
Assistant Professor
Department of Surgery
University of Alabama at Birmingham
Birmingham, Alabama

Joseph Rabin, MD
Associate Professor
Department of Surgery
University of Maryland School of Medicine
Baltimore, Maryland

Ravi S. Radhakrishnan, MD, MBA
Pediatric Surgeon-in-Chief
Department of Surgery
Program Director, Pediatric Surgery Fellowship
Department of Surgery
Professor (Tenured)
Departments of Surgery and Pediatrics
University of Texas Medical Branch
Galveston, Texas

Vinay Rao, MD, MPH
Assistant Professor
Department of Plastic Surgery
Brown University
Providence, Rhode Island

Chandrajit P. Raut, MD, MSc
Chief, Division of Surgical Oncology
Department of Surgery
Brigham and Women's Hospital;
Surgeon-in-Chief and Chair
Surgery
Surgery Director
Center for Sarcoma and Bone Oncology
Dana-Farber Cancer Institute;
Professor
Surgery
Harvard Medical School
Boston, Massachusetts

Kevin M. Reavis, MD
Foregut and Bariatric Surgeon
Foregut Surgery
The Oregon Clinic;
Medical Director
Foregut Surgery
Providence Portland Medical Center
Portland, Oregon

Richard James Redett, MD
Professor and Chair
Plastic and Reconstructive Surgery
Vice Dean for Clinical Affairs
Johns Hopkins School of Medicine;
Physician-in-Chief
Johns Hopkins Medicine
Baltimore, Maryland

Caroline E. Reinke, MD, MSHP
Clinical Associate Professor
Department of Surgery
Atrium Health, Wake Forest School of Medicine
Charlotte, North Carolina

Benjamin Rejowski, MD
Assistant Professor of Clinical Surgery
Department of Surgery
Southern Illinois University School of Medicine
Springfield, Illinois

Taylor Sohn Riall, MD, PhD
Professor
Department of Surgery
Associate Director
University of Arizona Cancer Center;
Division Chief, Surgical Oncology
Department of Surgery
University of Arizona
Tucson, Arizona

William O. Richards, MD
Professor and Chair
Department of Surgery
University of South Alabama College of Medicine
Mobile, Alabama

Kaitlin Ritter, MD
Assistant Professor of Surgery
Department of Surgery
MetroHealth Medical Center
Cleveland, Ohio

Christina L. Roland, MD, MS
Associate Professor
Chief, Sarcoma Surgery
Vice Chair, Research
University of Texas MD Anderson Cancer Center
Houston, Texas

Deborah M. Rooney, PhD
Associate Professor
Learning Health Sciences
University of Michigan
Ann Arbor, Michigan

Claire Rosen, MD, MSME
Resident Physician in General Surgery
Department of Surgery
Hospital of the University of Pennsylvania
Philadelphia, Pennsylvania

Michael Rosen, MD
Professor of Surgery
Chief, Division of Gastrointestinal Surgery
Northwestern University
Chicago, Illinois

Todd Kenneth Rosengart, MD
Professor and Chairman
Michael E. DeBakey Department of Surgery
Vice President for Hospital Operations and Quality Improvement
Baylor College of Medicine;
Professor
Texas Heart Institute
Houston, Texas

Joshua Alexandr Roshal, MD
General Surgery Resident
Department of Surgery
Brigham and Women's Hospital
Boston, Massachusetts;
Surgical Simulation and Education Research Fellow
Department of Surgery
University of Texas Medical Branch
Galveston, Texas

Nikki E. Rossetti, MD, MS
Resident Physician
Surgery
Research Fellow
Cardiothoracic Surgery
Washington University School of Medicine
St. Louis, Missouri

Margaret S. Roubaud, MD
Associate Professor
Department of Plastic and Reconstructive Surgery
University of Texas MD Anderson Cancer Center
Houston, Texas

Eva Roy, MD
Resident Physician
Plastic Surgery
Brigham and Women's Hospital
Boston, Massachusetts

Nobhojit Roy, MD, MPH, PhD
Senior Fellow
Surgery
The George Institute for Global Health India
New Delhi, India;
Formerly, Professor and Chief of Surgical Services
Department of Surgery
BARC Hospital
Anushakti Nagar, Mumbai, India;
Technical Officer
Surgery and Anaesthesia (Operative Care)
WHO Headquarters
Geneva, Switzerland

Rachel M. Russo, MD
Assistant Professor
Department of Surgery
University of California, Davis
Sacramento, California;
Assistant Professor
Surgery
Uniformed Services University of the Health Sciences
Bethesda, Maryland

Reid Sakamoto, MD
Clinical Assistant Professor
Department of Surgery
University of Hawaii John A. Burns School of Medicine
Honolulu, Hawaii

Sabrina E. Sanchez, MD, MPH
Associate Professor
Surgery
Boston Medical Center/Boston University Chobanian and Avedisian School of Medicine
Boston, Massachusetts

Uriel Sanchez-Rangel, MD
Resident Physician
Division of Plastic and Reconstructive Surgery
Brigham and Women's Hospital
Boston, Massachusetts

Warren Sandberg, MD, PhD
Professor and Chair
Department of Anesthesiology
Chief of Staff, Vanderbilt University Hospital
Vanderbilt University Medical Center
Nashville, Tennessee

Candice A.M. Sauder, MD, MEd
Associate Professor
Department of Surgery
Division of Surgical Oncology
University of California, Davis
Sacramento, California

John E. Scarborough, MD
Associate Professor
Department of Surgery
University of Wisconsin School of Medicine and Public Health
Madison, Wisconsin

August B. Schaeffer, MD
Resident in General Surgery
Department of Surgery
University of Texas Medical Branch
Galveston, Texas

Martin Allan Schreiber, MD
Professor of Surgery and Chief, Division of Trauma, Critical Care and Acute Care Surgery
Department of Surgery
Oregon Health & Science University
Portland, Oregon

Paul Schroder, MD, PhD
Clinical Instructor
Department of Surgery
University of Wisconsin School of Medicine and Public Health
Madison, Wisconsin

Richard D. Schulick, MD, MBA, FACS
Professor and Chair
Department of Surgery
University of Colorado School of Medicine
Director
University of Colorado Cancer Center
University of Colorado School of Medicine
Aurora, Colorado

Daniel Joseph Scott, MD
Professor of Surgery and Assistant Dean of Simulation
Department of Surgery and UT Southwestern Simulation Center
UT Southwestern Medical Center
Dallas, Texas

Sepehr Shabani, MD
Assistant Professor
Otolaryngology-Head and Neck Surgery
City of Hope National Medical Center
Duarte, California

Aakash Shah, MD
Cardiothoracic Resident
Department of Surgery
University of Maryland School of Medicine
Baltimore, Maryland

Ashish Shah, MD
Professor of Cardiac Surgery
Cardiac Surgery
Vanderbilt University Medical Center
Nashville, Tennessee

Paras Shah, MD
Assistant Professor
Department of Urology
Mayo Clinic
Rochester, Minnesota

Shimul A. Shah, MD, MHCM
Physician
Department of Surgery
University of Cincinnati Medical Center
Cincinnati, Ohio

Vidit Sharma, MD, MS
Assistant Professor
Department of Urology
Mayo Clinic
Rochester, Minnesota

Scott K. Sherman, MD
Clinical Assistant Professor
Department of Surgery
University of Iowa Carver College of Medicine;
Staff Surgeon
Surgery
Iowa City VA Medical Center
Iowa City, Iowa

Christine L. Shokrzadeh, MD, FACS
Assistant Professor
Department of Surgery
University of Texas Medical Branch
Galveston, Texas

Department of Surgery
Rush University Medical Center
Chicago, Illinois

Jeffrey M. Smith, MD, PCC
Orthopaedic Traumatologist
President
Orthopaedic Trauma and Fracture Specialists;
CEO
SurgeonMasters LLC
San Diego, California

Sawyer G. Smith, MD, MBA
Assistant Professor
Department of Surgery
University of California, Davis
Sacramento, California

Andrew Sobel, MD
Assistant Professor of Clinical Orthopaedic Surgery
Department of Orthopaedic Surgery
University of Pennsylvania
Philadelphia, Pennsylvania

Sabina M. Sorondo, MD
Vascular Surgery Resident
Division of Vascular Surgery
Post-Doctorate Fellow
Stanford Cardiovascular Institute
Stanford University
Palo Alto, California

Julie Ann Sosa, MD, MA, FACS, FSSO
Leon Goldman, MD Distinguished Professor and Chair
Department of Surgery
Professor
Department of Medicine
Affiliated Faculty
Philip R. Lee Institute for Health Policy Studies
University of California, San Francisco
San Francisco, California

Jason Sperry, MD, MPH
Professor
Trauma and General Surgery Section Chief
Andrew B. Peitzman Professor of Surgery
Department of Surgery
University of Pittsburgh
Pittsburgh, Pennsylvania

Maie St. John, MD, PhD
Professor and Chair
Head and Neck Surgery
David Geffen School of Medicine at UCLA
Los Angeles, California

Benjamin W. Starnes, MD
Chief, Vascular Surgery Division
Department of Surgery
University of Washington
Seattle, Washington

Deborah M. Stein, MD, MPH
Professor of Surgery
R Adams Cowley Shock Trauma Center
University of Maryland School of Medicine
Baltimore, Maryland

Melissa Stewart, MD, FACS
Assistant Professor
Department of Surgery
The University of Texas Health Science Center at Houston
Houston, Texas

David H. Stone, MD
Professor of Surgery
Section of Vascular Surgery
Dartmouth-Hitchcock Medical Center
Lebanon, New Hampshire

Michael Stoner, MD
Chief, Division of Vascular Surgery
Vascular Surgery
University of Rochester
Rochester, New York

Erin Alyse Strong, MD, MBA, MPH
Clinical Fellow
Surgical Oncology
Moffitt Cancer Center
Tampa, Florida

Vivian E. Strong, MD
Attending Surgeon/Professor of Surgery
Department of Surgery
Memorial Sloan Kettering Cancer Center;
Professor of Surgery
Department of Surgery
Weill Medical College of Cornell University
New York, New York

Christina M. Stuart, MD
Physician
Department of Surgery
Division of Cardiothoracic Surgery
University of Colorado Anschutz Medical Campus
Aurora, Colorado

Debra Sudan, MD
Professor of Surgery
Department of Surgery
Duke University Medical Center
Durham, North Carolina

John P. Sutyak, MD, EdM, MAMSE
Emeritus Professor
Department of Surgery
Southern Illinois University School of Medicine
Springfield, Illinois;
Chair ATLS
Committee on Trauma
American College of Surgeons
Chicago, Illinois

Luciano Guilherme Tastaldi, MD
Clinical Associate
Center for Abdominal Core Health, Digestive Disease and Surgery Institute
Cleveland Clinic Foundation
Cleveland, Ohio

Erin M. Taylor, MD
Associate Surgeon
Department of Surgery
Division of Plastic Surgery
Brigham and Women's Hospital/Harvard Medical School
Boston, Massachusetts

Pedro G. Teixeira, MD
Professor
Division Chief, Vascular Surgery
Cardiovascular and Thoracic Surgery
University of Texas at Austin
Austin, Texas

Jonathan Robert Thompson, MD, RPVI, FACS
Associate Professor of Surgery
Department of Surgery
University of Nebraska Medical Center
Omaha, Nebraska

Steven Tohmasi, MD, MPHS
General Surgery Resident
Department of Surgery
Washington University School of Medicine
St. Louis, Missouri

Betty Caroline Tong, MD, MHS
Associate Professor
Division of Cardiovascular and Thoracic Surgery
Duke University Medical Center
Durham, North Carolina

Alfonso Torquati, MD, MSCI
Helen Shedd Keith Professor and Chairman
Department of Surgery
Rush University
Chicago, Illinois

Grant B. Torres, MS
Predoctoral Research Fellow
Plastic Surgery
University of Texas Medical Branch
Galveston, Texas

Douglas Tran, MD
Cardiothoracic Surgery Resident
Cardiac Surgery
University of Maryland
Baltimore, Maryland

Susan Tsai, MD, MHS
Professor
Department of Surgery
Ohio State University
Columbus, Ohio

Allan Tsung, MD
Chair
Department of Surgery
University of Virginia
Charlottesville, Virginia

Ayaka Tsutsumi, MD
Research Affiliate
Colon and Rectal Surgery
Yale University
New Haven, Connecticut

Michael Turturro, MD
Physician
Department of Surgery
Columbia University Medical Center
New York, New York

Douglas S. Tyler, MD, MSHCT
Professor of Surgery
Associate Chair of Community Operations and Strategy
Department of Surgery
The University of North Carolina at Chapel Hill
Chapel Hill, North Carolina

Rindi Uhlich, MD, MSPH
Medical Director, TICU
Surgery
Chippenham Hospital
Richmond, Virginia

Timothy Ullmann, MD
Assistant Professor
Surgery
Albany Medical College
Albany, New York

Raj Vaghjiani, MD
Assistant Professor of Surgery
Surgical Oncology
University of Texas Medical Branch
Galveston, Texas

Konstantinos Votanopoulos, MD, PhD
Associate Professor
Surgery
Wake Forest University
Winston Salem, North Carolina

Heather Wachtel, MD
Associate Professor
Department of Surgery
University of Pennsylvania
Philadelphia, Pennsylvania

John Patrick Walker, MD
Professor
Department of Surgery
University of Texas Medical Branch
Galveston, Texas

Claire Watkins, MD, MS
Clinical Assistant Professor
Cardiothoracic Surgery
Stanford University
Stanford, California

Ronald J. Weigel, MD, PhD, MBA
EA Crowell Jr. Professor and Chair
Department of Surgery
University of Iowa
Iowa City, Iowa;
Medical Director
Cancer Programs
American College of Surgeons
Chicago, Illinois

Roi Weiser, MD
Assistant Professor
Department of Surgical Oncology
Assistant Professor
Department of Breast Surgical Oncology
University of Texas MD Anderson Cancer Center
Houston, Texas

Andrew Well, MD, MPH, MSHCT
Assistant Professor
Surgery and Perioperative Care
Dell Medical School at The University of Texas at Austin;
Assistant Director for Health Transformation and Patient Experience
Texas Center for Pediatric and Congenital Heart Disease;

PREFACE

I am deeply honored to have been appointed as the Editor-in-Chief for the 22nd edition of the *Sabiston Textbook of Surgery.* This textbook has played a pivotal role in my surgical education since my entry into medical school, much like it has for countless surgeons around the globe. When I entered the Duke General Surgery Training program in 1985, Dr. Sabiston had recently completed his work on the 13th edition. During my residency, I had the opportunity to contribute a chapter titled “Surgical Aspects of the Acquired Immunodeficiency Syndrome” to the 14th edition, drawing from my expertise gained during 2 years (1987–1989) in the department’s Surgical Virology research lab, where I studied the newly identified human immunodeficiency virus. As I transitioned to a junior faculty position at Duke, I continued my involvement with the textbook by contributing another chapter on the surgical aspects of the acquired immunodeficiency syndrome for the 15th edition.

When the editorship passed from Dr. Sabiston to Dr. Courtney Townsend in 2001, I could not have imagined that I would eventually follow in Dr. Townsend’s footsteps as Chairman of the Department of Surgery at the University of Texas Medical Branch (UTMB). Upon my transition to UTMB in 2014, Dr. Townsend had just finalized the 20th edition. While at UTMB, I contributed to the 21st edition by co-authoring a chapter on melanoma and cutaneous malignancies.

As I take on the role of Editor-in-Chief for the 22nd edition, I am excited to guide a text that has significantly influenced my surgical career. In an era characterized by rapidly advancing technologies and swift information dissemination, producing a textbook that remains relevant and current poses a challenge. We have endeavored to uphold the tradition of delivering a core, evidence-based text authored by leading surgical experts. Our approach involved engaging multiple authorities from various institutions to provide diverse perspectives on contentious issues. Additionally, we significantly expanded sections that focus on patient outcomes, including chapters on healthcare disparities, global surgery, quality measurement, competence definition, and surgical simulation.

Recognizing the increasing specialization within the field of surgery, this edition emphasizes the vital role of genetic and genomic information in managing disease processes, evolving from strategies solely based on histologic pathology. Most areas of patient care necessitate a multidisciplinary approach, involving collaboration among surgeons, anesthesiologists, medical specialists, pathologists, and radiologists, which we have highlighted throughout this edition. Furthermore, new technical advancements have introduced innovative methods for performing procedures—whether through open, laparoscopic, robotic, or endovascular techniques—all of which are thoroughly reviewed both individually and in the context of their relevant chapters. We are also collaborating with experts to produce podcasts, allowing readers to glean valuable insights from various chapters. Our objective is to furnish a comprehensive, evidence-based resource that serves not only students and trainees but also established surgeons seeking surgical perspectives on clinical challenges.

Douglas S. Tyler, MD, MSHCT

FOREWORD

First published as the *Textbook of Surgery,* edited by Dr. Frederick Christopher, in 1936, the textbook underwent four editions over the next 14 years. In 1956, the textbook was published as *Christopher's Textbook of Surgery,* edited by Dr. Loyal Davis, with three editions under the same title. In 1972, the tenth edition of the textbook was published as the *Davis-Christopher Textbook of Surgery,* edited by Dr. David C. Sabiston, Jr. The tenth edition represented an increase in volume by one-third, expanding from 40 to 57 chapters.[1] New chapters were included in the areas of cardiovascular surgery and transplantation, with more than twice the number of authors from the United States, Canada, England, and Australia. The subtitle of the tenth edition was "The Biologic Basis of Modern Surgical Practice," which stressed the biologic principles underlying surgical practice, with "voluminous" references for each chapter. The focus on biologic principles backed up by extensive references remained a defining feature of the subsequent editions with Dr. Sabiston as editor. A review by Dr. Claude E. Welch of the 11th edition published in 1977 noted that the textbook stressed the scientific basis of modern surgical practice but added, "However, a word to prospective customers is this: buy the two-volume edition if you plan to use it for bedtime reading."[2] Beginning with the 13th edition published in 1986, the textbook became known as the *Sabiston Textbook of Surgery.* In 2001, the 16th edition of the *Sabiston Textbook of Surgery* was published with editor Dr. Courtney M. Townsend and his co-editors Drs. R. Daniel Beauchamp, Kenneth L. Mattox, and B. Mark Evers. They published five subsequent editions of the *Sabiston Textbook of Surgery,* with the 21st edition being published in 2021.

Welcome to the 22nd edition of the *Sabiston Textbook of Surgery,* edited by Dr. Douglas S. Tyler. The 22nd edition continues the tradition of the *Sabiston Textbook of Surgery* being the most comprehensive and authoritative reference for the modern practice of the evolving field of general surgery. The text follows a clear and logical progression of sections that begin by covering Surgical Training and Quality Control and continuing with Perioperative Management, followed by sections on specific disease processes including Trauma and Critical Care, Transplantation and Immunology, Surgical Oncology, Endocrine Disorders, Abdominal Wall Hernias, Alimentary Tract, Vascular Surgery, Cardiothoracic Surgery, and ending with a section on Specialties in Surgery: Subspecialty Considerations Relevant for the General Surgeon that includes Pediatric Surgery, Maternal-Fetal Surgery, Hand Surgery, Gynecology Surgery, and Urologic Surgery. Authors of each chapter are individuals who are recognized leaders in their specialty in surgery and who have made seminal contributions to advance the care of surgical patients in their area of expertise. Many new chapters have been added since the last edition, which reflects the rapid evolution and expanding knowledge content in general surgery. Several new chapters related to surgical training, surgical simulation, training in innovative procedures involving minimally invasive techniques, and surgical certification provide important information on the rapidly expanding field of surgical education and maintenance of technical competence. New chapters have been added that address health disparities and focus on access to care and improving equity in surgical care; these include the chapters of "Social Determinants of Health and Their Impact on Surgical Outcomes," "Surgical Quality Improvement Programs," "Patient Reported Outcomes," "Telehealth in Surgery," "Global Surgery," and "Surgical Considerations in the Transgender Patient." Two new chapters have been added that focus on "Surgeon Health and Well-Being" and the rapidly evolving field of Surgeon Health: Ergonomics. Major new updates have been provided in chapters that focus on The evolving role of the microbiome in surgical practice, surgical considerations in palliative care, soft tissue infections, management of urologic trauma, management of pediatric trauma, management of chronic wounds, lung transplantation, GI stromal tumors, peritoneal malignancies and HIPEC, lymphadenopathy, carcinoid tumors, percutaneous heart procedures, and ECMO. Each chapter is beautifully illustrated with figures and intraoperative photographs. The *Sabiston Textbook of Surgery* is a critical reference for medical students and general surgery residents in training, providing key insight and in-depth information for the care of the surgical patient. All of these highly comprehensive chapters include extensive references to support the evidence-based literature that provides the biologic basis for current surgical practice.

The 22nd Edition of *Sabiston's Textbook of Surgery* is available in print and eBook format, providing an enhanced learning experience with text, figures, videos, and references.

ACKNOWLEDGMENTS

We would like to express our gratitude to Kristine Feeherty, Joanie Milnes, and Jessica McCool for their invaluable editing and administrative support, which have greatly enhanced the quality of this textbook. Additionally, we extend our heartfelt appreciation to all the chapter authors who, despite their demanding schedules, have collaborated with us to impart their knowledge and insights. Lastly, we wish to acknowledge the contributions of Drs. Joshua Rochal and Pat Walker for their role in launching a podcast companion series for this textbook.

CONTENTS

SECTION I SURGICAL TRAINING AND QUALITY CONTROL

1 **Surgical Education: Past, Present, and Future** *(online only)*
Rachael C. Acker, Jennifer LaFemina, and Rachel R. Kelz

2 **Surgical Simulation and New Ways to Optimize Performance** *(online only)*
Daniel B. Jones, Roy Phitayakorn, Deborah Rooney, Daniel J. Scott, and Carla M. Pugh

3 **Certification of Surgeon Competence** *(online only)*
Daniel L. Dent, Tim Nelson, and Andrew Jones

4 **Preoperative Risk Assessment and Alterations in the COVID-19 Era** *(online only)*
Christina M. Stuart, Shipra Arya, and Robert Alexander Meguid

5 **Social Determinants of Health and Their Impact on Surgical Outcomes** *(online only)*
Kathleen Jarrell, Robert S.D. Higgins, Colin A. Martin, and Oluwadamilola M. Fayanju

6 **Critical Assessment of Surgical Outcomes and Health Services Research** *(online only)*
Benjamin S. Brooke, Rachel A. Greenup, and Alex Bernard Haynes

7 **Surgical Quality Improvement Programs** *(online only)*
Kristen Kaiser, Karl Bilimoria, and Ryan Merkow

8 **Patient-Reported Outcomes** *(online only)*
Mariam N. Hantouli, Giana H. Davidson, and Anne P. Ehlers

9 **Safety in the Surgical Environment** *(online only)*
Aditi Balakrishna, Michael P. DeWane, Haytham M.A. Kaafarani, and Warren S. Sandberg

10 **Advances and Training Considerations in Robotic Surgery** *(online only)*
Sarah Hays, Brian Boone, Herbert Zeh, and Melissa Hogg

11 **Advances and Training Considerations in Laparoscopic Surgery** *(online only)*
Joshua Alexandr Roshal, Alexander Perez, and Aurora Pryor

12 **Advances and Training Considerations in Endoscopy and Endoscopic Surgery** *(online only)*
Claire B. Rosen, Reid Sakamoto, Kevin M. Reavis, and Daniel A. Hashimoto

13 **Telehealth in Surgery** *(online only)*
Caroline E. Reinke and Feibi Zheng

14 **Health Inequities and Disparities in Surgery** *(online only)*
Tanya L. Zakrison, Anthony Douglas, Mihir Chaudhary, Marc de Moya, and Cherisse Berry

15 **Global Surgery** *(online only)*
Sudha Jayaraman, Anthony Charles, Michelle Huyser, Maria Fernanda Jimenez, and Nobhojit Roy

16 **Ethics and Professionalism in Surgery** *(online only)*
Peter Angelos and John D. Mellinger

17 **Surgeon Health: Ergonomics** *(online only)*
Yewande Alimi and Geeta Lal

18 **Surgeon Health and Well-Being** *(online only)*
Carrie Cunningham, Tasha Hughes, Jeffrey M. Smith, and Taylor S. Riall

SECTION II PERIOPERATIVE MANAGEMENT, 1

19 **Principles of Preoperative and Operative Surgery,** 2
Chioma Moneme, Allan Tsung, Reid B. Adams, and Victor M. Zaydfudim

20 **Anesthesiology Principles, Pain Management, and Sedation,** 38
Aditi Balakrishna, Monica Bhutiani, and Christina J. Hayhurst

21 **Optimizing Surgical Outcomes: Prehabilitation and Rehabilitation,** 68
Lindsay Welton, Emily Finlayson, and Elizabeth Wick

22 **Enhanced Recovery After Surgery (ERAS): Evidence-Based Perioperative Pathways to Optimize Outcomes,** 74
Olle Ljungqvist, Hans D. de Boer, and Gregg Nelson

23 **Wound Healing,** 88
Jadie Y. Moon and Katherine A. Gallagher

24 **The Evolving Role of the Microbiome in Surgical Practice** *(online only)*
Robert Keskey and John C. Alverdy

25 **Surgical Site Infections,** 118
Melissa K. Stewart and Lillian S. Kao

26 **Surgical Complications: Overview and Grading,** 126
Fariba Abbassi, Milo A. Puhan, and Pierre-Alain Clavien

27 **Surgery in the Geriatric Patient,** 144
Vanita Ahuja, Ayaka Tsutsumi, and Sandhya A. Lagoo-Deenadayalan

28 **Surgery in the Pregnant Patient,** 157
Rachel M. Russo, Gregory J. Jurkovich, Diana L. Farmer, and Candice A.M. Sauder

29 **Surgical Considerations in the Transgender Patient,** 177
Uriel Sanchez-Rangel, Rachel Bluebond-Langner, and Devin O'Brien Coon

30 **Surgical Palliative Care,** 189
Orly N. Farber, Erin A. Strong, and Elizabeth J. Lilley

31 **Advanced Analytics and Artificial Intelligence Applications in Surgery** *(online only)*
Jason M. Aubrey, Teodor Grantcharov, and Gretchen Purcell Jackson

SECTION III TRAUMA AND CRITICAL CARE, 201

32 **The Inflammatory Response,** 202
Letitia E. Bible and Alicia M. Mohr

33 **Shock, Electrolytes, and Fluid,** 221
Paige Farley, Sawyer G. Smith, Jason L. Sperry, and Martin Allan Schreiber

34 **Metabolism and Nutrition in Surgical Patients,** 269
Catherine L. McKnight, Stephanie Eosten Joyce, Brian J. Daley, and Kimberly A. Davis

35 **Primary Soft Tissue Infections,** 291
Rondi B. Gelbard and Rindi Uhlich

36 **Management of Acute Trauma,** 301
Sharon M. Henry, Melike Harfouche, Meaghan Broderick, Benjamin Rejowski, Brandt Whitehurst, and John P. Sutyak

37 **The Difficult Abdominal Wall,** 356
Whitney R. Jenson, Oliver L. Gunter, and Clay Cothren Burlew

38 **Management of Vascular Trauma,** 370
Mary Bokenkamp, Joshua Crapps, Joseph DuBose, Pedro G. Teixeira, and Carlos V.R. Brown

39 **Management of Urologic Trauma,** 388
Hiren V. Patel and Benjamin N. Breyer

40 **Emergency Care of Musculoskeletal Injuries,** 397
Anna N. Miller and Mitchel R. Obey

41 **Emergency Care of Neurologic Injuries,** 436
Amelia W. Maiga, Rachel Hooper, Paul Cederna, Hani Chanbour, Iyan Younus, Soren Jonzzon, Scott L. Zuckerman, and Mayur B. Patel

42 **Management of Pediatric Trauma,** 462
William R. Johnston, Meera Kotagal, Michael L. Nance, and Gary W. Nace

43 **Burns,** 479
Steven A. Kahn and Steven E. Wolf

44 **The Outdoors—Venomous Bites and Stings and Environmental Exposure** *(online only)*
John Patrick Walker and Gregory J. Jurkovich

45 **Management of Chronic Wounds,** 503
Camila Franco-Mesa, Grant B. Torres, Ludwik K. Branski, and Linda G. Phillips

46 **Surgical Critical Care,** 528
Justin S. Hatchimonji, Seema Anandalwar, Niels D. Martin, and Deborah M. Stein

47 **Moving Operating Room Procedures to the Intensive Care Unit,** 551
Bradley M. Dennis, Rachel D. Appelbaum, and Jose J. Diaz

48 **The Surgeon's Role in Disaster Management,** 559
David Zonies, Michael Cheatham, and Joseph Johnson

SECTION IV TRANSPLANTATION AND IMMUNOLOGY, 572

49 **Transplantation Immunobiology and Immunosuppression,** 573
William H. Kitchens, Idelberto Raul Badell, and Andrew B. Adams

50 **Regenerative Medicine and Its Applications to Surgery** *(online only)*
Mitchell R. Ladd and Anthony Atala

51 **Surgical Considerations in Transplant Patients Undergoing Nontransplant-Related Procedures and Operating in Patients With Portal Hypertension,** 615
Hassan Aziz, Jenna N. Whitrock, and Shimul A. Shah

52 **Kidney Transplantation,** 624
Muhammad Umaid Rabbani and Jayme E. Locke

53 **Liver Transplantation,** 638
Franklin Olumba, William C. Chapman Sr., and Majella Doyle

54 **Pancreas Transplantation,** 651
Tsukasa Nakamura, Jon S. Odorico, James F. Markmann, and Paul M. Schroder

55 **Islet Transplantation,** 664
Divyansh Agarwal, Tina Bharani, Chengyang Liu, Vijay Bhoj, and Ali Naji

56 **Small Bowel Transplantation,** 669
Imran J. Anwar and Debra L. Sudan

57 **Heart Transplantation,** 679
Jeffrey E. Keenan, Chetan Pasrija, Ashish S. Shah, and Carmelo A. Milano

58 **Lung Transplantation,** 707
Jason M. Gauthier, Douglas Tran, Christine L. Lau, Alexander S. Krupnick, and Daniel Kreisel

59 **Soft Tissue Transplantation** *(online only)*
Andrew N. Atia, Detlev Erdmann, Ines C. Lin, L. Scott Levin, Kathleen O'Neill, Neil O'Kelly, Richard Redett, Lioba Huelsboemer, and Bohdan Pomahac

SECTION V SURGICAL ONCOLOGY, 721

60 **Tumor Biology and Tumor Markers** *(online only)*
Abdurrahman T. Abdelzaher, Edmond W. Box III, John Herndon, S. Peter Goedegebuure, Ryan C. Fields, and Nipun B. Merchant

61 **Tumor Immunology and Immunotherapy** *(online only)*
Genevieve M. Boland, Joseph G. Crompton, James S. Economou, and James C. Yang

62 **Surgical Considerations in Cancer Patients** *(online only)*
Paul R. Burchard, Richard D. Schulick, and David C. Linehan

63 **Melanoma and Cutaneous Malignancies,** 722
Michael E. Egger, Georgia M. Beasley, Douglas S. Tyler, and Kelly M. McMasters

64 **Sarcomas of the Soft Tissues, Retroperitoneum, and Bone,** 750
Heather G. Lyu, Elizabeth J. Lilley, Shalin S. Patel, Chandrajit P. Raut, and Christina L. Roland

65 **Gastrointestinal Stromal Tumors,** 778
Mark Antkowiak, Ronald P. DeMatteo, and Jason K. Sicklick

66 **Benign Diseases of Head and Neck,** 792

77 **Neuroendocrine Neoplasms (Carcinoid Tumors),** 1035
Andrea Gillis, Sophie Dream, and Herbert Chen

78 **The Multiple Endocrine Neoplasia Syndromes,** 1042
Samuel J. Enumah, Gerard M. Doherty, and Elizabeth G. Grubbs

SECTION VII ABDOMINAL WALL HERNIAS, 1053

79 **Preoperative Management of the Hernia Patient,** 1054
Sergio Mazzola Poli de Figueiredo, Aldo Fafaj, Benjamin Poulose, Alfredo Carbonell, and Michael J. Rosen

80 **Ventral Hernias,** 1063
Richard Lu, Julie L. Holihan, Thomas Clements, Genevieve Chartrand, Luciano Tastaldi, Paul Taehoon Kim, and Igor Belyansky

81 **Hernias of the Abdominal Wall: Atypical Locations,** 1083
Dina Podolsky, Philip George, David John Morrell, Michael Turturro, and Yuri Novitsky

82 **Inguinal Hernias,** 1091
Richard Lu, Jorge Daes, David Lourie, Alexandra Z. Agathis, Luciano Tastaldi, Leandro Totti Cavazzola, Brian P. Jacob, and Flavio Malcher

SECTION VIII ALIMENTARY TRACT, 1107

83 **Benign Esophageal Disorders,** 1108
Marco G. Patti, Fernando A. Herbella, Karan Chhabra, and Matthew M. Hutter

84 **Esophageal Cancer,** 1136
Ngoc-Quynh Chu, Betty Caroline Tong, Thomas D'Amico, David Harpole, and Daniela Molena

85 **The Acute Abdomen,** 1155
Kaitlin A. Ritter, Mary I. Junak, John E. Scarborough, and Vanessa P. Ho

86 **Stomach,** 1166
David A. "Sasha" Mahvi and David M. Mahvi

87 **Gastric Cancer,** 1192
Sam Yoon, Joshua Leinwand, and Vivian E. Strong

88 **Biliary System,** 1213
Bryan Clary, Ryan Broderick, August B. Schaeffer, Jennifer Moffett, and Rebekah White

89 **The Liver,** 1249
Laleh Melstrom, Kevin Labadie, and Yuman Fong

90 **Secondary Tumors of the Liver,** 1306
Reed I. Ayabe, Mengyuan Liu, Michael I. D'Angelica, and Yun Shin Chun

91 **Small Intestine,** 1320
B. Mark Evers

92 **Exocrine Pancreas,** 1374
Alykhan M. Premji and Timothy R. Donahue

93 **Pancreatic Cancer,** 1401
Susan Tsai and Douglas B. Evans

94 **The Appendix,** 1415
Sabrina E. Sanchez, Daniel Counihan, Elishana Kanu, and Dan G. Blazer 3rd

95 **Colon and Rectum,** 1429
Nir Horesh, Sameh Emile, and Steven D. Wexner

96 **Cancers of the Colon, Rectum, and Anus,** 1491
Matthew Kalady, David Liska, and Mohammad Abbass

97 **Benign Anorectal Disorders,** 1515
Joshua I.S. Bleier, Paul Tarver Hernandez, and Lea Lowenfeld

98 **Acute Gastrointestinal Hemorrhage,** 1544
Dimitrios Moris, Jacob Greenberg, and Theodore N. Pappas

99 **Morbid Obesity,** 1554
Alfonso Torquati, Nicholas J. Skertich, Philip Omotosho, and William O. Richards

SECTION IX VASCULAR SURGERY, 1579

100 **Hemostasis and Thrombosis,** 1580
Ashley A. Peters, Sarah A. Loh, Alan Dardik, and Vivian Gahtan

101 **Contemporary Management of Carotid Disease,** 1603
Rohini J. Patel, Jesse A. Columbo, David H. Stone, and Mahmoud B. Malas

102 **Aortic Disease,** 1620
Abe DeAnda, Mitchell W. Cox, and Matthew J. Eagleton

103 **Peripheral Occlusive Disease,** 1643
Elizabeth G. King, Katharine L. McGinigle, and Alik Farber

104 **Extremity Amputations in the Modern Era: Indications, Technique, and Outcomes,** 1676
Jani Lee and Raj G. Vaghjiani

105 **Peripheral Aneurysmal Disease,** 1688
Joshua T. Geiger, Dawn Coleman, and Michael C. Stoner

106 **Visceral Ischemic Syndromes: Acute and Chronic Mesenteric Ischemia,** 1709
Sabina M. Sorondo, Blake E. Murphy, Benjamin W. Starnes, and Jason T. Lee

107 **Dialysis Access,** 1721
Yana Etkin and Karen Woo

108 **Venous Disease,** 1730
Christine L. Shokrzadeh, Alexis N. Davis, and Ruth L. Bush

109 **The Lymphatics,** 1750
Jonathan R. Thompson and Iraklis I. Pipinos

SECTION X CARDIOTHORACIC SURGERY, 1759

110 **Lung, Chest Wall, Pleura, and Mediastinum,** 1760
Nikki E. Rossetti, Steven Tohmasi, Mark W. Onaitis, and Benjamin D. Kozower

111 **Acquired Heart Disease: Coronary Artery Disease,** 1806
Ifeanyi D. Chinedozi, Edward P. Chen, and Jennifer S. Lawton

112 **Acquired Heart Disease: Valvular,** 1842
Marc R. Moon, Puja Kachroo, and Todd K. Rosengart

113 **Congenital Heart Disease,** 1870
Andrew Well and Chuck D. Fraser, Jr.

114 **Pulmonary Embolism: Acute and Chronic,** 1908
Hiroko Nemoto, Jill R. Higgins, and Michael M. Madani

115 **Percutaneous Heart Procedures** *(online only)*
A Claire Watkins, Perry Seo Choi, Anson Michael Lee, and Y. Joseph Woo

116 **Advances in Extracorporeal Membrane Oxygenation: Techniques, Applications, and Management,** 1925
Douglas Tran, Aakash Shah, Christine L. Lau, and Joseph Rabin

SECTION XI SPECIALTIES IN SURGERY: SUB-SPECIALTY CONSIDERATIONS RELEVANT FOR THE GENERAL SURGEON, 1944

117 **Pediatric Surgery,** 1945
Dai H Chung, Edward M. Barksdale, Jr., Bindi J. Naik-Mathuria, and Ravi S. Radhakrishnan

118 **Maternal-Fetal Surgery** *(online only)*
Andrew Bain, Mary T. Austin, and Diana Farmer

EXPERT INSIGHTS: THE SABISTON PODCAST

PODCAST EDITORS

Douglas Tyler, MD, MSHCT
Professor of Surgery
Associate Chair of Community Operations and Strategy
Department of Surgery
The University of North Carolina at Chapel Hill
Chapel Hill, North Carolina

Joshua A. Roshal, MD
General Surgery Resident
Department of Surgery
Brigham and Women's Hospital
Boston, Massachusetts;
Surgical Simulation and Education Research Fellow
Department of Surgery
University of Texas Medical Branch
Galveston, Texas

J. Patrick Walker, MD, FACS
Professor of Surgery
University of Texas Medical Branch
Galveston, Texas

CONTENTS

1. Acute Abdomen
2. Acute Limb Ischemia
3. Breast Disease
4. Inguinal Hernia
5. Gallbladder Disease

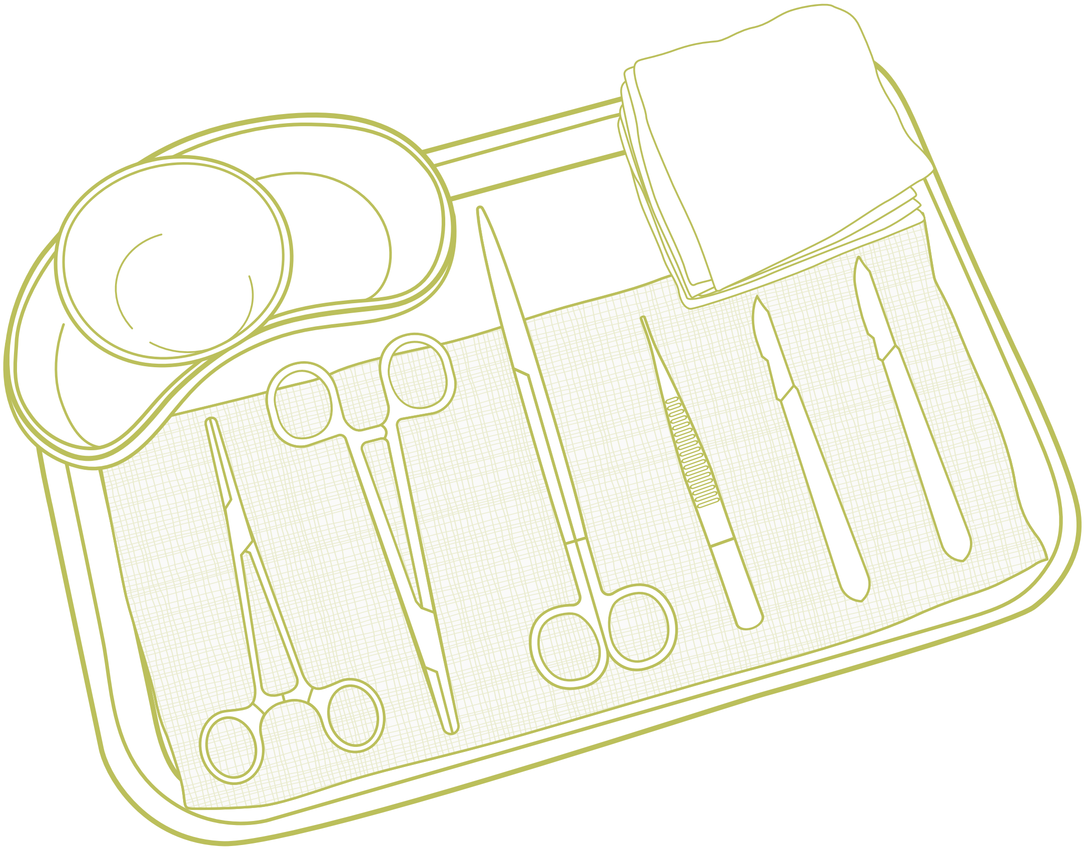
To access this title's podcasts, please scan the QR code with a mobile device.

SECTION I

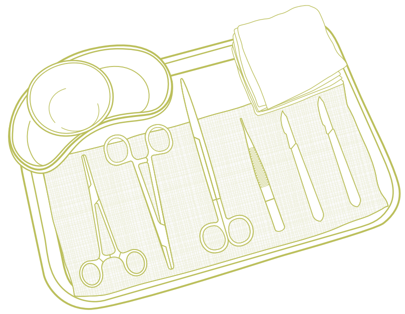
Surgical Training and Quality Control

The following chapters appear only on Elsevier eBooks+:

1 Surgical Education: Past, Present, and Future
2 Surgical Simulation and New Ways to Optimize Performance
3 Certification of Surgeon Competence
4 Preoperative Risk Assessment and Alterations in the COVID-19 Era
5 Social Determinants of Health and Their Impact on Surgical Outcomes
6 Critical Assessment of Surgical Outcomes and Health Service Research
7 Surgical Quality Improvement Programs
8 Patient Reported Outcomes
9 Safety in the Surgical Environment
10 Advances and Training Considerations in Robotic Surgery
11 Advances and Training Considerations in Laparoscopic Surgery
12 Advances and Training Considerations in Endoscopy and Endoscopic Surgery
13 Telehealth in Surgery
14 Health Inequities and Disparities in Surgery
15 Global Surgery
16 Ethics and Professionalism in Surgery
17 Surgeon Health: Ergonomics
18 Surgeon Health and Well-Being



1 CHAPTER



Surgical Education: Past, Present, and Future

Rachael C. Acker, Jennifer LaFemina, and Rachel R. Kelz

OUTLINE

Historical Evolution of Surgical Education
The Modern Era of Surgical Education
Assessment and Evaluation in Surgical Education
Modern Challenges and Innovations in Surgical Education
  Duty Hour Reform
  Resident Well-Being and Mistreatment
  Team-Based Learning, Interprofessional Education, and Simulation
  Evidence-Based Medicine
  Diversity, Equity, and Inclusion
Ethical Considerations in Surgical Education
Surgical Education Across Specialties
  General Surgery
  Orthopedic Surgery
  Neurosurgery
  Cardiac Surgery
The Impact of COVID-19 on Surgical Education
Technologic Advancements and the Future of Surgical Education
Continuous Professional Development and Lifelong Learning
Conclusion

HISTORICAL EVOLUTION OF SURGICAL EDUCATION

The first evidence of surgery likely dates back to as early as 4900 BCE, with archaeologic evidence of trephination, the practice of drilling holes into the skull, for treatment of migraines or to rid the body of "evil spirits."[1,2] Evidence of other procedures such as splinting, reductions for dislocations, and various strategies for wound care have been documented across many continents and ancient empires in the intervening 6000 years.[1] The Middle Ages and Renaissance saw the rise of barber-surgeons, or practitioners who traveled around performing tooth extractions, bloodletting, wound care, and occasionally, excisions of other skin and soft tissue abnormalities. Andreas Vesalius wrote his anatomic textbook *De Humani Corporis Fabrica Libri Septem* in 1543 during this time period, shifting the focus from animal experimentation to human dissection to provide a better understanding of human anatomy.[1] Despite the subsequent increase in understanding of anatomy and human physiology, the practice of surgery would remain largely limited by the lack of antiseptic technique and pain control until the late 1800s with the introduction of Listerian antisepsis and anesthesia.[3,4]

In the 18th century, medical education in the American colonies consisted only of apprenticeships modeled after the English and European systems. William Shippen, Benjamin Rush, and John Morgan established the first medical school in America in 1765 in Philadelphia, eventually integrating with the University of Pennsylvania.[5] By 1813, there were four additional medical schools in the United States—King's College (Columbia), Yale, Harvard, and Dartmouth—and this number continued to increase throughout the 1800s. However, during this period there were no standards for the degrees these medical colleges bestowed, and access to this formal education was very limited.[5] State medical societies began cropping up, and in 1821, Connecticut's medical society created a board examination, becoming the first state to enforce passage of an exam as a prerequisite to practice medicine.[5] When it opened in 1893, Johns Hopkins became the first medical school to require a 4-year university degree before matriculation.[5] In 1910, variation in the quality of medical school education in the United States led Abraham Flexner to publish a famous report grading medical schools based on three tiers (using criteria for curricula, faculty, facilities, and entry requirements) and recommending closure of schools in the lowest tier (120 of 162 in existence).[6,7] This represented the first paradigm shift toward the standardization of undergraduate medical education in the United States.[5]

From the late 1800s to early 1900s in the United States, postgraduate medical education remained limited with rare internship positions across the country.[5] Most surgical procedures were performed by general practitioners, with very few surgical courses offered at a limited number of medical schools, usually lasting only a few weeks.[8] Those who could afford the expense often traveled to Germany, or other institutions in Europe, for surgical training where the first formal surgical training programs were developed in the 1870s (the first of which was in Berlin, a state-sponsored university that hired dedicated professors of surgery and combined education in the basic sciences, experimental research, independent autopsies, and clinical experience).[8,9]

In 1889, after completing an internship at Bellevue Hospital in New York and his surgical studies in Germany and Austria, William Halsted returned to the United States to create the first formal surgical training program at Johns Hopkins Hospital.[8] At the time, William Osler was the first chief of medicine. The "school of surgery" was modeled after the German system and emphasized graduated autonomy in patient care.[8] It was a pyramidal model in which multiple trainees started surgical residency and only one would ultimately become the chief resident and graduate as a surgeon.[7] Of note, there was no specific length of time for this training. The goal was to produce high-quality surgeons with whatever variable length of time was required for a resident to be deemed ready for independent practice by Dr. Halsted.[7,8]

By the turn of the 20th century, there were 10 surgical residencies in the United States modeled after Halsted's "school of surgery," increasing to about 35 by the mid-1930s.[8] Over the course of the first half of the 20th century, several initiatives drastically transformed the organization of surgical practice and education. Founded in 1913 by Franklin Martin, The American College of Surgeons (ACS) established some national standards for practicing surgery but did not make any training recommendations to achieve them.[10] Subsequently, in 1937, Evarts Graham (Chair of Surgery at Washington University) founded the American Board of Surgery (ABS) and required 3 years of graded training after internship.[8] He also advocated for hiring full-time medical school faculty to allow physicians more time to focus on research and teaching, without needing to support a private practice.[11] Additionally, Edward Churchill, at Massachusetts General Hospital, recognized the rapidly growing need for more surgeons. As a result, in 1939, he created the first surgical residency program with a rectangular model. In this model, every resident who entered the program was eligible to graduate.[7]

Around this time, the ACS created a Committee on Graduate Training in Surgery and in 1938 began requiring two postgraduate years of training after internship for its members. The committee began performing site visits to evaluate residency programs, an effort that was already being performed in parallel across medical specialties by the American Medical Association (AMA).[7,8] Further, in 1941, the ACS established more rigorous requirements for surgical training programs, creating national standards for the quantity and types of procedures residents needed to perform, while adopting Churchill's rectangular model to meet the demand of a growing surgical patient population. The G.I. Bill, which was signed at the conclusion of World War II, significantly expanded residency positions. It provided government funding for residency training for veterans and created many new residency programs through the Veterans Affairs Administration (VA; the VA also preferentially hired board-certified surgeons, which further promoted this more formal training pathway).[8] With these changes, the number of surgical residencies almost doubled between 1945 and 1950.[8] However, this dramatic growth came at a cost as many of the programs created were not of high quality. Most of the programs did not undergo inspection, and the number of graduates who could not pass board exams increased.[8] This led the AMA, ACS, and ABS, who all had their own independent and discrete approval processes, to unite and create a Conference Committee on Graduate Training in Surgery in 1950, which subsequently became the Residency Review Committee in 1955. The new uniform system for accrediting training programs could now be separated from the board examination process that certified graduates for practice.[7] In the subsequent years, the Liaison Committee for Graduate Medical Education (LCGME) was created to bring together accreditation committees across specialties in 1972.[7] Unfortunately, the politics and power struggle between the multiple organizations involved (AMA, American Board of Medical Societies, American Hospital Association, Association of American Medical Colleges [AAMC]) hindered its progress. The LCGME eventually dissolved and our current accreditation body, the Accreditation Council for Graduate Medical Education (ACGME), did not reorganize until 1981, requiring several more years to create its accreditation process.[7]

From its earliest days, surgical training has been an experiential process where learners undergo on-the-job training. Due to the expense and inefficiency of this approach, an overhaul of the system was initiated in 1999. The ACGME launched the Next Accreditation System to create a new dawn for an outcomes-based system of surgical education. The goal of the system was to move from a time-based system based on experiential training to one centered on the acquisition of core competencies determined by expert consensus regarding the skills necessary to fulfill the professional obligations of a surgeon. This transition is at the epicenter of modern surgical education.

THE MODERN ERA OF SURGICAL EDUCATION

Heralded by the transition to the Next Accreditation System, Competency-Based Medical Education (CBME) is now at the center point of the graduate medical education (GME) dialogue. This "new" approach to medical education finds its roots in work by Edward Churchill in the 1930s, who, as part of his rectangular model-based surgical training system, voiced a need for flexibility in training to support trainee growth. He noted that "a frozen five-year curriculum…is unthinkable as it allows no latitude for the development of individual interests and proficiencies."[12]

The conceptual model of CBME recognizes that learners have different aptitudes, and as such, they warrant time-variable training in their mastery of learning goals. The goal of CBME focuses on the outcomes of training, rather than maintaining the previous, time-required traditions observed in medical training, including surgery.[13] In GME, this outcome is the learner-centered goal of obtaining a fixed level of proficiency, or mastery, in at least one medical specialty, such that the learner will graduate and be safe for independent practice.

With the reorganization of the ACGME, a priority was placed on creating a developmental approach to assessment without overprescribing accreditation standards. This is the foundation for CBME in the United States. In 1999, this led to the development of the six core competencies for medical trainees in GME: Patient Care and Procedural Skills (PC), Medical Knowledge (MK), Systems-Based Practice (SBP), Practice-Based Learning and Improvement (PBLI), Professionalism (PR), and Interpersonal and Communication Skills (ICS).[14,15] As described by Ten Cate, competencies are "learnable, durable, and measurable [abilities] to execute a specific, integrative task that is part of a full range of tasks that constitute the medical profession."[16,17] However, challenges in operationalizing core competencies included a lack of understanding of the meaning of competencies among trainees and faculty, variability in education and clinical outcomes, and difficulty aligning competencies across both the curriculum and the assessment of training.

In 2013, the ACGME introduced the Milestones to describe a trainee's progression along each core competency from novice to expert and to aid in more accurate evaluation.[15] Originally developed in co-sponsorship by the ACMGE and the American Board of Medical Specialties (ABMS) certification boards, Milestones were designed to facilitate a method to feasibly operationalize the competencies and provide a measurable framework of observable skills, behaviors, and medical knowledge that describe a trainee's overall level (assessed every 6 months). By improving the quality of assessment, such that programs can determine a resident's ability, identify gaps in the educational framework to improve the curriculum, and judge progress as well as the resident's readiness to enter independent practice, the Milestones were a major step forward in providing public accountability for medical education. The Milestones 2.0 (revised in 2018–20) added more consistency to the subcompetencies and harmonization of non-MK and non-PC Milestones.[18]

Whereas the ACGME described the transition to an outcomes-based system in 1999, the Royal College of Physicians and Surgeons of Canada (RCPSC) took the greatest strides toward CBME with the with the introduction of "CanMEDS" in 2005.[19] With a common primary aim to define the competencies physicians must possess to serve the needs of patients and support the desired outcomes, CanMEDS defined seven qualities all physicians must portray, or "Physician Roles": Medical Expert, Communicator, Collaborator, Health Advocate, Manager, Scholar, and Professional.[20] The CanMEDS program then moved one step closer to CBME with the introduction of an alternative type of milestones designed around the discrete skills known as *entrustable professional activities* (EPAs).[21]

Today, the EPAs have catapulted to the forefront of the CBME movement. EPAs are most commonly defined as "a unit of professional practice that can be fully entrusted to a trainee once he or she has demonstrated the necessary competence to execute the activity unsupervised."[22] These units allow assessment of competence in a holistic, forward-viewing manner that is directly observable.

Implementation of EPAs across disciplines in the Netherlands proved to allow a flexible, time-variable (on average, training was shortened by 3 months), competency-based national curriculum while preserving safe patient care.[23] The RCPSC has similarly implemented EPAs, with outcomes under ongoing review.[24,25] A national pilot study of ABS-written EPAs was recently completed across 28 general surgery programs in the United States. The pilot included five EPAs representing the most common procedures in ACGME case logs and those of practice-ready, independent general surgeons. Implementation was feasible and was shown to provide meaningful data to entrust graduating postgraduate year (PGY) 5 general surgery residents as practice-ready, independent general surgeons.[26] In July 2023 EPAs became required of all US general surgery training programs. Together with the ACGME Milestones, the EPA assessments are designed to support decisions around advancement to the next phase of learning and toward the ultimate goal of independent practice, regardless of the time required to achieve it.[24,26]

In principle, CBME is the solution to achieve the critical outcome of training residents who achieve independence by the time of graduation. However, implementation of the various components of CBME is not without challenges. The burden of assessment, performance-based strategies, and an adverse impact on educator and trainee well-being have been reported.[27] Critical to the future of CBME is an ongoing, iterative, and transparent process of the assessment of educational outcomes with these new models and discussion of strategies to reduce challenges.

Similar dialogues of competence occur in undergraduate medical education (UME), particularly in light of variability around preparedness upon the transition to residency.[28] The goal of medical school curricula is to prepare all graduates equitably with core knowledge across specialties. Yet, challenges remain around the acquisition of specialty-specific skills that incoming program directors have identified as essential for the entering PGY1.[29] In a parallel paradigm to the ABS EPAs in general surgery, the AAMC Core EPAs for Entering Residency outline activities incoming interns should be able to conduct without direct supervision at the start of training. These remain under study in terms of their extent and role in UME training but could serve as an opportunity to foster and optimize a longitudinal transition from UME to GME.[28] Additional general surgery–specific requirements to prepare senior medical school students for general surgery residency, based upon program and societal feedback, have been published and could be incorporated.[29]

ASSESSMENT AND EVALUATION IN SURGICAL EDUCATION

In athletics, performance is judged with specific, objective metrics such as time in swimming, goals scored in soccer, and scores composed of a combination of execution and skill-based difficulty level in gymnastics or diving. In each arena, these metrics allow individuals to benchmark their performance against competitors and against their own personal performance history to gauge improvement. Medical and surgical education, however, do not have the same explicit criteria with which to evaluate performance. Furthermore, whereas rehearsal in athletics is reliant on scheduled, intentional practice, surgical education relies largely on chance encounters in which learning is dependent on the patients and diseases that present themselves.

CBME is executed through competency-based medical training (CBMT), which includes stipulation for assessment. The importance of effective assessment has been widely published and aligns to the original description of deliberate practice. This description involves modifying the learning environment such that learners are exposed to a range of experiences that foster gradual progression and improvement via immediate feedback.[30] Frequent and actionable feedback is integral to the ongoing progress of learners.[31]

Therefore, medical and surgical education have always been reliant on feedback, both as a way to progress (nonevaluative, formative feedback) and as a mechanism for assessment and evaluation (summative feedback). The importance of formative feedback is well recognized, and there is a wealth of research focused on delivery, timing, and content of feedback[32] as well as a recent emphasis on both operative and nonoperative clinical coaching.[33] Most established methods for providing formative feedback to residents rely on end-of-rotation feedback or standardized patient encounters. However, the recently developed applications, such as the System for Improving and Measuring Procedural Learning (SIMPL) smartphone-based application, have increased the frequency of workplace-based assessments (or real-time observations of clinical encounters) and have been adopted by several residency programs.[34] In-service training exams, such as the ABS In-Training Exam (ABSITE), were created as assessments to provide formative feedback and predict the likelihood of passing board exams at the end of training. However, the question of how to evaluate and assess surgical training is constantly evolving and will require significantly more work before matching the objectivity that exists in other fields.

Determination of competency in Halsted's model consisted of experts deciding when individuals could perform surgery independently, but the model lacked criteria to determine this achievement. Given the need to standardize the assessment of trainee progress and performance, the ACGME helped to develop the Milestones[2] (see previously), which describe different behaviors of a practicing surgeon/physician. Residents are rated on a scale from 1 to 5, with a rating of 4 set as the target for graduation at the end of residency. These Milestones are determined by clinical competency committees (CCCs; mandated by the ACGME in 2019), which consist of faculty that meets every 6 months to discuss and evaluate a trainee's progress. The new EPAs, adopted in July 2023 by the ABS for use in general surgery residencies (see the section "The Modern Era of Surgical Evaluation"), attempt to define "units of work," or specific measurable activities of clinical care (nonoperative and operative). The activities can be directly observed and evaluated,[35] but these too will rely on faculty feedback, and it remains to be seen how they will move the field closer toward competency-based education.

As the focus on patient safety increases, and the "see one, do one, teach one" paradigm becomes more distant, simulation is an increasingly enticing method of both technical skills development and evaluation.[36–38] Much like learning to play an instrument can be broken down into quantifiable steps—learning notes, site reading, chords, songs, and finally, more advanced compositions—simulation provides the opportunity to practice discrete skills without risk to patients. There is currently a great deal of diversity in the type of simulation-based training used for formative training, including a variety of models (robotic, virtual reality, animal models, cadavers, high fidelity models, etc.) as well as a few validated assessment tools. For example, the Objective Structured Assessment of Technical Skills (OSATS) test grades examinees on a series of technical exercises on inanimate objects.[39] However, it is not clear how these models translate to clinical practice and intraoperative performance. Therefore, there is also no consensus on which simulated performance metrics are best to measure.

In GME, simulation is not currently used for surgical credentialing.[39] However, the passage of the Fundamentals of Laparoscopic Surgery (FLS) and Fundamentals of Endoscopic Surgery (FES) exams by the Society of American Gastrointestinal and Endoscopic Surgeons (SAGES) is a requirement of trainees in many individual surgery programs. However, the way in which these simulations are graded is not publicly known, thus making tracking individual improvement challenging and limiting the value of the formative feedback they can provide. The use of video-based assessment for either intraoperative or simulation-based performance is another relatively new application, and it will require consensus and development of standards before use as a formal evaluation of trainees. The benefits include decreased operative time (feedback is provided after the procedure), increased objectivity (although there is some evidence of bias in evaluations if the identity of the trainee is apparent in the recording), and increased efficiency in evaluations, especially with use of video editing.[40]

Finally, a novel area of research that has potential to provide the most objective feedback/data in surgical training comes in the form of patient data. Studies have linked patient claims data with surgeon identifiers to evaluate new versus experienced surgeon outcomes,[41] the effects of education reform on new surgeon performance,[42] and the quality of residency programs based on the patient outcomes of their graduates.[43,44] A recent study examining the relationship between surgical resident Milestones achievement at the end of training and their patient outcomes after the transition to independent practice (including 30-day mortality and complication rates) showed no significant association.[45] This study indicates that the current method of evaluating trainees may not be examining the most clinically relevant metrics or that the ratings of the residents at the completion of training may not provide meaningful information on their actual skill levels.

Despite the advances in our understanding of feedback and efforts to achieve competency-based feedback, we are still reliant on subjective metrics of performance based on faculty/expert evaluations. This leaves surgical education assessment vulnerable to bias. Various studies in the surgical, emergency medicine, and internal medicine literature have demonstrated that females are slower to progress in the achievement of Milestones, compared with males,[46–48] and the data on individuals of races/ethnicities underrepresented in medicine (URiM) are lacking. These data highlight the need for significant faculty development to standardize the EPAs and make them the most useful they can be. It also presents the need to develop more objective outcomes metrics for use in surgical training, perhaps by harnessing patient data including that captured in the electronic health record.

Finally, harnessing these data to assess training programs on many metrics, including patient care, will help programs benchmark themselves against one another in multiple domains, including physician wellness. Sellers and colleagues proposed three tiers for evaluating training programs with tier 1 including credentialing, board certification, and patient outcomes; tier 2 including the time required to train surgeons and the impact of this training on physical and mental well-being; and tier 3 including a higher-level assessment of the long-term implications of training on the individual such as fertility and family planning as well as other opportunity costs.[49] Although its easiest to focus on tier 1, with an increased awareness on resident well-being, placing emphasis on alternative performance metrics for programs aside from patient outcomes is needed to advance the field and allow for surgical career longevity.

MODERN CHALLENGES AND INNOVATIONS IN SURGICAL EDUCATION

Duty Hour Reform

Libby Zion was a college freshman who died of serotonin syndrome in a New York hospital attributed to errors performed by the overworked medical house staff responsible for her care. Her death highlighted entrenched problems in GME. To address the most tangible problem, sleep deprivation, in 2003 the ACGME mandated resident work hour restrictions. The exact criteria of these restrictions have been modified over the years without evidence to support their modification.

The primary concern was the effect of duty hour reform on training. Great concern regarding the ability to safely care for patients in academic centers with contracted resident duty hours exists as do concerns regarding the ability for residents to be adequately trained with fewer training hours. These concerns motivated completion of several studies to examine the impact of duty hour reform on patient safety. The iCOMPARE study performed a randomized trial in Internal Medicine showing that duty hour flexibility did not negatively impact mortality and other secondary outcomes, including patient safety, among patients treated by residents with restricted duty hours.[50] In general surgery, Kelz and coworkers looked beyond training to the patient outcomes of newly graduated surgeons. They showed no significant impact of the work hour restrictions experienced during training on patient mortality (and several secondary outcomes) of newly graduated surgeons before and after implementation of duty hour reform.[51]

The aptly named Flexibility in Duty Hours Requirements for Surgical Trainees (FIRST) study was the first national, prospective, and randomized trial to assess the effects of duty hour reform on patient and surgical resident outcomes during training. Residents with less restrictive duty hours showed nonsignificant differences in patient mortality, serious patient complications, and overall satisfaction with well-being and education compared with peers assigned to the new restricted duty hours. Even more so, improvements in satisfaction in a number of secondary outcomes including, but not limited to, professionalism, ability to conduct research, continuity of care, and perceived patient safety were observed in the flexible policies group (i.e., those with less restrictive duty hours).[52]

Resident Well-Being and Mistreatment

In the FIRST trial, more than a third of trainees reported weekly burnout symptoms. Although this was not the primary outcome of the study, it prompted further investigation into the work environment, launching resident well-being and mistreatment into the forefront of the GME dialogue. A follow-up survey distributed to general surgery residents revealed that nearly a third of the respondents reported gender discrimination, 17% reported racial discrimination, 10% reported sexual harassment, and approximately 30% reported verbal and/or physical abuse, with all being reported more commonly by female residents.[53] Additionally, nearly 40% reported daily burnout and more than 4% reported suicidal thoughts in the prior year.[53] LGBTQ+ trainees represent a particularly high-risk group for mistreatment and suicidality.[54] These results were striking and unexpected, igniting a movement to improve the resident work environment, minimize burnout, and eliminate mistreatment. The Surgical Education Culture Optimization through Targeted Interventions based on National Comparative Data (SECOND) Trial was subsequently initiated and remains ongoing. This prospective, randomized trial randomizes surgical residency programs to receive a Wellness Toolkit and annual report of resident wellness or control.

Team-Based Learning, Interprofessional Education, and Simulation

CBME requires a comprehensive curriculum inclusive of team-based competencies, including those related to nontechnical skills (NTS). NTS are demonstrated, for example, through decision-making processes, team communication, leadership, and situational awareness. Such skills allow learners and future surgeons to make accurate, patient-centered decisions; execute reliable, effective, and timely communication; and reduce medical errors.

Interprofessional training has been widely studied, uniformly helps to achieve these competency goals, and yields benefits in patient safety and quality. This is particularly important in modern day practice given that complex patient care is more commonly provided through an interdisciplinary network of providers. Failure of NTS, particularly in poor communication, is highlighted in nearly 80% of malpractice claims and is frequently cited as a cause of adverse events and poor patient outcomes.[55,56]

Simulation can play an integral role in both procedural and interprofessional, team-based learning. As a learner-centered model, simulation allows users to repeat exercises in a safe environment, without harm to patients, and to obtain an objective and measurable outcome in which an intervention can be made. As such, it can enhance the quality of care, particularly for high-risk, uncommon scenarios.[57,58] For instance, in a simulated crisis with teams comprised of surgeons, anesthesiologists, and nurses, higher NTS led to faster crisis resolution.[59]

Evidence-Based Medicine

Within surgical training, evidence-based medicine (EBM) is the backbone of lifelong learning and is essential to progression through the Milestone levels. The incorporation of EBM with the Practice-Based Learning and Improvement Milestone allows individuals to critically evaluate a growing body of literature with the goal of improving patient outcomes. Steps to incorporate EBM in surgical training include defining the problem, searching and critically evaluating the available data, applying the result to practice, and reassessing outcomes.[60]

Although essential, implementation of EBM can prove elusive due to barriers of acquisition, appraisal, and application. These barriers are broad in nature and can include a lack of education about the definition of EBM, a perceived or actual lack of mentorship or leadership that incorporates EBM, and feelings of helplessness including those related to challenges such as time constraints. Essential to EBM curriculum development is education about the meaning of EBM, practice of EBM in real-time during various clinical care scenarios, and leadership example (locally, regionally, and nationally) of EBM incorporation into clinical practice and resident education.[61,62]

Diversity, Equity, and Inclusion

The motivations for a diverse surgical workforce are clear: Patients who are URiM are more likely to seek out and positively view the care they receive if they are cared for by a provider of a similar race/ethnicity; trainees who are URiM are more likely to care for patients from medically underserved communities.[63,64] Additionally, team members with diverse backgrounds and experiences provide a breadth of perspectives and drive the development of effective patient-centric strategies and innovation. In surgery, residents and faculty from underrepresented backgrounds are even more underrepresented than in other medical specialties,[65] and females (who make up about half of the national medical school cohort) are less likely to enter academic medicine, be promoted, and progress to positions of leadership.[66–68]

Increased representation requires solutions across each phase of the pipeline and relies on an awareness of the current state and commitment and allyship from leadership. As it relates to surgical education and the surgical workforce, a number of recommendations regarding optimal strategies for recruitment have been put forth. Holistic review, or the evaluation of an applicant's unique attributes and experiences, as well as the alignment of these attributes with the values of the surgical residency program, is the cornerstone and has been shown to effectively increase representation across groups by gender, race, and ethnicity.[69] Additional innovations, including but not limited to URiM-focused visiting clerkships and situational judgment tests (SJTs), have shown promising results in increasing representation of URiM applicants through the recruitment process.[70,71]

Programmatic policies and practices that support retention and training in an inclusive environment are critical to the success of trainees, particularly those who might be at higher risk or are marginalized. For instance, recognition and resolution of situations where implicit bias permeates opportunities, evaluations, and operative experience can maximize the success of residents.[72] Implicit bias will be discussed later in this chapter. Key performance goals have been set forth by the American Surgical Association.[66]

ETHICAL CONSIDERATIONS IN SURGICAL EDUCATION

Implicit biases are developed through exposure to stereotypes and judgments attributed to a specific group that may be untrue. Although the individual may not be aware, this misinformation integrates these perceptions into the subconscious, subsequently influencing behavior toward the impacted group. Over time, our minds become programmed to "make sense of things" so that data can be filtered and acted upon quickly. Implicit bias is an unknowingly negative mechanism that compartmentalizes information to achieve this goal.

Implicit bias is evident throughout resident recruitment and retention. For instance, to address ballooning application numbers, many programs set initial screening parameters including, but not limited to, standardized tests (United States Medical Licensing Examination [USMLE], Comprehensive Osteopathic Medical Licensing Examination [COMLEX], etc.) and Medical Student Performance Evaluation (MSPE). Although there are data that standardized test scores place groups such as females and those who are URiM (who may not have the same resources for test preparation) at a disadvantage, they continue to be heavily relied upon for decisions around interview invitation and rank. For instance, in an Internal Medicine applicant cohort, African American applicants were threefold to sixfold less likely to receive an interview for each incremental increase in Step 1 on the scoring ruberic.[73] In another study of more than 6000 MSPEs from US Medical degree graduates, there were significant differences in standout words (e.g., exceptional, best, and outstanding), which were more commonly used in the MSPEs of White applicants compared with URiM applicants. Although there was some correlation to Step 1 score, race and ethnicity remained the only significant difference when the analysis was controlled for Step 1.[74] The MSPEs of general surgery applicants showed similar language differences, with those of URiM having more communal rather than agentic terms.[75] Letters of recommendation (LORs) for male surgery applicants were more likely to be longer, use standout adjectives, and make references to achievements, ability, leadership, scholarship, and other aspects compared with female applicants. LORs for female counterparts were more likely to incorporate general terms, grindstone words, and words related to physical descriptions or ones that raised doubt. Given the value placed on the MSPEs, standardized tests, and LORs, these qualitative differences likely affect the success of these marginalized groups.[76] For example, URiM applicants to general surgery had a disproportionately lower likelihood of interview selection.[77]

Not surprisingly, these biases can persist into residency training through evaluations, which are essential determinations of competence. Male residents in surgical specialties receive rotation evaluations with more positive and standout words compared with their female counterparts.[78] Milestones may help to mitigate some implicit bias by utilizing a potentially more objective evaluative system. However, in a striking review of Milestone distribution between male and female Emergency Medicine residents, Milestones were similar between genders at the beginning of training but progressively showed discordance with female residents finishing training 3 to 4 months behind.[47] Incorporation of the EPAs have shown some early positive outcomes with faculty assessments having no difference between gender.[79] However, these data are from a single-center study, and it is not clear if the neutrality of the results will generalize across all training programs.

Mitigating implicit bias in recruitment and retention involves both individual and organizational intentionality. Central to this aim are awareness and capacity to evaluate and reflect upon one's own biases. Multiple publicly available sites can help individuals identify subconscious perceptions to which they may not be aware.[80] Gaining awareness, making an effort to understand alternative judgments (including expanding one's circle to cultivate broader awareness and sensitivity), and executing solutions are starting points for each individual involved in resident recruitment and retention.

Programmatically, a number of new innovations may reduce implicit bias within recruitment. Standardized LORs may improve interrater reliability and serve as a more objective measure of an applicant's talent. The standardized Orthopedics LORs negate the previously significant differences in standout words between gender and race/ethnicity, such that they are no longer significant.[81] SJTs also contribute as an objective measure of personal traits associated with systems-based learning, practice-based learning, and interpersonal communication. These can be applied at different stages of recruitment and can be tailored to specific program values to optimize program-applicant alignment. Use of an SJT in several general surgery residencies showed that about a third of applicants invited to interview would have otherwise not met the interview threshold set by USMLE Step 1 cutoffs; incorporating SJTs significantly increased the likelihood of URiM applicants invited to interview.[82]

Interview conduct offers additional opportunities to intentionally reduce implicit bias. Following the selection of candidates based upon value and position definition, the use of a structured process (e.g., similar interview platform offered to all candidates; standardized questions; a panel of diverse individuals with implicit bias training; standardized scoring mechanisms, such as the use of a talent scorecard) can help to transform the interview into a more objective and quantifiable event by which to better assess candidates and plan for the training and retention of a diverse workforce prepared to care for the population.

In addition to the ethical considerations inherent to the selection and retention of surgical trainees, medical educators must maintain a clear commitment to the patients treated within academic medical centers. The training environment must provide a culture of safety in which trainees can learn and receive a graduated level of responsibility while maintaining a commitment to the highest standards of surgical quality and safety. Evidence suggests that the site of training ultimately dictates performance upon the transition to independent practice, which places greater responsibility on surgical educators to ensure training that results in optimal patient outcomes. Training practices differ across programs, and the system of education must take ownership of this variation in training to standardize surgical care at the population level.[83,84] This will require a coordinated effort across educational bodies and the governance organizations that oversee training, credentialing, and privileging.

The EPAs offer a new taxonomy to facilitate the adoption of CBME. Perhaps the inclusion of EPAs will release medical education from a time-based system where trainees require a form of supervision for all activities until graduation. This new approach may additionally prompt a system based on competence in which surgical educators will be able to allow residents in training, who demonstrate practice-ready skills, to continue to learn the totality of the profession's demands while simultaneously earning the right to practice specific activities independently, before transitioning to complete independence. There is precedent for this approach in nursing where arguments exist to allow practitioners to use their skills to the fullest extent of their scope of practice.[85] This tactic would maximize the societal gain of surgical education without exposing the population to undue risk. For now, until evidence of the clinical reliability of the EPAs emerge, surgical educators must honor their obligation to the public and create a clinical learning environment that balances training with safety to fulfill their obligation to the field of surgery. Hopefully, in the not too distant future, education and safety will be the same as we will be able to measure competence and move people along to (or hold people back from) independent practice based on skill, rather than time.

SURGICAL EDUCATION ACROSS SPECIALTIES

Until the 1900s there was just one field of surgery. As the field evolved, focused expertise in a subset of diseases and procedures, often centered on one organ system, led to the emergence of different specialties. Students interested in surgery began with a general education, usually as an apprentice, in fundamental surgical skills and principles. General surgery, the most broad-based discipline, emerged from this model as the foundational cornerstone of surgery and surgical education. In the early 1900s surgical specialization was formalized with the establishment of independent boards, which dramatically influenced the structure of surgical education. In response to the increased demands of the information age brought about by scientific development of the Internet, new educational paradigms emerged to parallel the specialty-specific demands.

Today, medical education in the United States begins with a bachelor's degree (usually 4 years), followed by a medical degree (usually 4 years), a residency in a surgical specialty (usually 5–6 clinical years), and then finally an optional fellowship (usually 1–3 years). Clinical training paradigms have evolved with the introduction of early specialization and integrated programs designed to allow early specialty differentiation. Rather than a common start in a general surgery internship or residency, followed by subspecialty training, these new patterns of education eliminate the unnecessary time and expense of broad training for many specialties. Regardless of the training paradigm, in addition to the clinical training time, many surgical specialties encourage 6 months to 2 to 3 years of research training as a commitment to contribute to the advancement of the particular field.

Several universal factors have impacted training across specialties. Increased scrutiny of patient outcomes has demanded more supervision and reduction in trainee autonomy. The development of minimally invasive techniques has affected education at all levels because education in these methods differs from the historical training of open operations. Shortened inpatient lengths of stay and a shift toward outpatient surgery have challenged the training in preoperative and postoperative care. Historically, all of this occurred under the observation of the trainees, and now efforts to impart this knowledge must be intentional and deliberate or the trainee remains ignorant. Finally, the introduction of simulation, and its availability across specialties, has opened a new opportunity in surgical training that has yet to be optimized.

Across specialties, governing bodies and local educators have addressed each of these obstacles with their own unique approach. The remainder of this section will highlight some of the specialties, with an emphasis on the different ways in which they have adapted to the changing world around us. The examples will not be exhaustive or comprehensive, just mainly enough to allow the reader to appreciate the heterogeneity of the training experience, the complexity of surgical education, and the important role that it plays in the future of the field.

General Surgery: A Model for Collaboration Across Stakeholders

General surgery is its own specialty and remains the backbone for many surgical fields.[86] As such, educational innovation may be slower in this field because there is less urgency to evolve. Further, with increasing specialization, the number of fellowship programs has risen dramatically. In many cases, this has led to a shift in the case volumes of surgical residents, and perhaps delays in the attainment of competence. Because of substantial variation in training across programs, the ABS has become increasingly committed to unifying the training experience. One effort, the formation of the Surgical Council on Resident Education (SCORE), is designed to encourage dialogue across the six major organizations involved in the oversight of surgical education.

SCORE has a major stake in shaping the future of general surgery. The first decision this group made was to maintain the duration of the training period at 5 clinical years. Next, using expert consensus to drive decision-making, the SCORE established the scope of the training required to become board certified in general surgery. Now, the SCORE is tasked with maintaining a curriculum in general surgery. Currently, the ABS and the SCORE are working to facilitate the shift to CBME via the launch of the general surgery EPAs discussed earlier in this chapter.

Orthopedic Surgery: A Leader in Competency-Based Medical Education

Orthopedic surgery evolved early into a specialty, distinct from general surgery.[87] Although the training requires a minimum of 5 clinical years of residency, advanced training in joints and other subspecialities remains common. Orthopedic surgery has been one of the most adventurous fields for surgical education, with the common adoption of cadaveric training labs, use of simulation, testing of virtual learning, and, on the international scene, the first to pilot a competency-based curriculum in 2009.

The University of Toronto's Division of Orthopaedic Surgery was the first surgical training program, worldwide, to pilot a curriculum relevant to the trainee entering independent practice, with clear and specialty-specific milestones and intense assessment of the established competencies.[21,88] Outcomes from the original implementation were positive and ultimately led to a national implementation.[21] Ongoing metrics are followed actively by the RCPSC and suggest that with the Competence by Design model residents receive more actionable feedback, there is more engagement in learning, and struggling residents are identified sooner, among other positive outcomes.[25]

Neurosurgery: A Game Changer in the Education of Surgeon-Scientists

Neurosurgery faces many challenges related to the delicate and high-stakes nature of all neurosurgical procedures.[89,90] However, despite these challenges, neurosurgery has been highly productive in the realm of training surgeon-scientists. Many credit the introduction of specialized funding mechanisms, via traditional agencies such as the National Institutes of Health, for the tremendous growth in the number of neurosurgeon-scientists relative to the steep decline seen within other surgical specialties. However, funding opportunities alone do not foster success in this pipeline. For surgical education to incorporate the need for the rigorous scientific training of surgeons, the training process must recognize and provide the necessary time and resources required to acquire the unique skills needed to succeed as a scientist with a clinical practice. The fundamental requirements include an appropriate environment, mentorship, scientific training, and a personalized development plan. Many programs within neurosurgery have embraced this mission and created a course to inspire the other surgical specialties.

Cardiac Surgery: A Specialty Responsive to the Educational Implications of Clinical Demands

In response to trainee demands for protracted training time and the evolution of the field to incorporate new approaches to surgery that necessitate training in open and minimally invasive approaches, cardiac surgery implemented an integrated pathway.[91] This new programmatic approach to teach budding cardiac surgeons how to master the field in 6 years, rather than 7 to 10 years, introduced a dramatic shift in the curricular content. Rather than focusing on the holistic approach to broad surgical training including the mastery of surgical intensive care, the integrated program contracted the surgical training time to allow multidisciplinary training in fields critical to performance as a cardiac surgeon. The new training path includes education in competencies historically considered outside the domain of surgical training. As such, the integrated education includes rotations in cardiology, anesthesiology, and radiology services, to list a few. Controversy exists regarding the superiority of one training paradigm over the other, and patient-level outcomes between the integrated and traditional path have not yet been examined.

Broadly, several specialties such as orthopedic surgery, neurosurgery, otolaryngology, and ophthalmology have been considered independent of general surgery for decades because of the early formation of independent certification boards. Other specialties like plastic surgery, vascular surgery, and cardiothoracic surgery sit at the intersection of independence and subspecialities because there remain dual pathways to certification, one of which includes passing through general surgery. Colorectal surgery, endocrine surgery, breast surgery, transplant surgery, pediatric surgery, and complex surgical oncology remain subspecialties of general surgery, although alternative training pathways are under consideration. Finally, subspecialities like acute care surgery and trauma surgery remain general surgery fields based on the breadth of practice and the absence of independent specialty board representation. These relationships have contributed to the personalities of the individual fields and their subsequent approaches to education.

THE IMPACT OF COVID-19 ON SURGICAL EDUCATION

The COVID-19 pandemic had a significant impact on the surgical world. In the United States, beginning in March 2020, elective operations were canceled, medical and surgical staff were deployed to COVID-19 units, and nonessential personnel, such as medical school students, were furloughed. Therefore, this period necessitated and catalyzed several changes in the delivery and context of surgical education.

First, the pandemic impacted provider well-being and increased cases of burnout. A scoping review of burnout in surgeons and surgical trainees during COVID-19 showed rates of burnout ranging from 10% to as high as 86%, depending on the study.[92] Given the decrease in elective cases, many trainees worried about not getting enough operative cases or hands-on experience.[92] To continue to allow for trainee progression, this prompted the ABS, Royal College of Surgeons, and other accreditation bodies to decrease various residency case requirements during the pandemic.[93] However, redeployment to the intensive care unit (ICU) and other areas of the hospital allowed some surgical residents and attendings to develop and reinforce nonoperative skills such as communication, leadership, and teamwork as they worked with members from various specialties to care for COVID patients.[93]

The pandemic also catalyzed the integration of many technology platforms for the purposes of delivering educational content. Many medical schools used different modalities to teach anatomy when cadaveric dissection became unfeasible. These modalities included virtual or augmented reality, videos, three-dimensional printing, plastination (method of preserving body parts by replacing certain structures with plastics so specimens do not decay), and even social media, such as X, formally Twitter, for education content dissemination. Several studies showed that, in anatomy, medical school student performance and test scores, using these models, were statistically equivalent to traditional cadaveric dissection.[94] Other learning resources that existed previously, but became increasingly used during the pandemic, include access to electronic textbooks, SCORE and other online surgical learning platforms, online surgical videos, and home or video surgical simulation training such as makeshift laparoscopic trainers. Many resident and medical school student didactics and conferences became virtual during this time,[95] and many programs have maintained these hybrid options to increase attendance for individuals at satellite hospital sites. Moving forward, having this virtual technology more widely available for training may help us standardize the educational content delivered to all trainees.

During the 2020–21 academic year, recruitment processes also dramatically changed with the adoption of virtual interviews, virtual open houses, and virtual site visits.[96] Virtual recruitment offers several benefits, including decreased cost. Before the pandemic, the total cost of annual recruitment ranged between $61,000 and $129,000 for residency programs,[97] and an average of $6300 in applicant travel expenses.[96] Additionally, unforeseen benefits included attending interviews, without as much disruption during the fourth year of medical school or during residency (for fellowship interviews),[96] virtual social hours, and uncovering other methods of sharing information.[97] However, some studies indicate lower faculty scores of virtual candidate interviews when compared with in-person interviews; this may be because of challenges with eye contact, as well as presence over video.[96] Further, in a national survey study of plastic surgery residency and fellowship program directors, 75% and 63%, respectively, felt that they were not able to assess applicant fit as well with virtual interviews, with a majority reporting difficulty determining an applicant's personality, communication skills, and "ability to function as a trainee."[98] In a recent study of interns who underwent the first virtual application cycle in 2020–21, the majority felt that they were able to understand the content of the program with virtual interviews, but not the culture of the program or a feel for the city without an in-person experience.[99] It ultimately remains to be seen how programs and trainees will be impacted by virtual recruitment (in terms of happiness, well-being, sense of belonging, etc.) in their current program, and which version of the process will persist as time passes.

TECHNOLOGIC ADVANCEMENTS AND THE FUTURE OF SURGICAL EDUCATION

Before the onset of the COVID-19 pandemic, the personal and professional costs of surgical education on young surgeons, the consequent implications for surgical competence, and a looming surgeon shortage put pressure on regulatory organizations and surgical educators to rethink the process and restructure the approach to surgical training. Naturally, educators looked to technology to facilitate the rapid transfer of information from teachers to learners, with the aim of accelerating the pace of surgical skill acquisition. Many of the initiatives focus on tools that provide a substitute for experiential training (e.g., simulation), with automation of feedback and assessment.

The integration of virtual reality and augmented reality has ushered in a new era of immersive surgical training.[100] Virtual reality platforms create realistic, three-dimensional simulations that allow trainees to navigate through intricate anatomical structures and practice procedures in a risk-free environment. Augmented reality overlays digital information onto the surgeon's view, providing real-time guidance during live surgeries. These applications not only enhance spatial awareness and procedural skills but also facilitate collaborative learning experiences across physically distant settings.

The vast majority of technology designed and tested to advance surgical education targets technical skills training. Simulation using benchtop and screen-based virtual reality represents the most frequent setting. Evidence suggests that artificial intelligence holds tremendous promise for providing critical feedback to guide development and ultimately differentiate skill levels.

Robotic-assisted surgery, with its enhanced dexterity and precision, allows for realistic simulation of complex procedures, offering trainees a hands-on experience in a controlled environment. Although training programs include videos and the equipment to practice the physician skills, an absence of expert feedback or critical appraisal, based on performance in the simulated activity, limit the utility of these programs.[101] As the field continues to evolve, the symbiotic relationship between human skill and technologic prowess promises to redefine the standards of surgical education.

Advancements in connectivity and telecommunication technologies have opened doors to telementoring and remote surgical education.[102] Surgeons can now receive real-time guidance from mentors located around the world, fostering a global community of knowledge exchange. Telementoring platforms allow for livestreaming of surgeries, enabling trainees to observe and learn from experts without geographic constraints. As these technologies continue to mature, the possibilities for remote surgical education are poised to expand, ensuring widespread access to mentorship and expertise that transcend geographic boundaries.

The evolution of teaching methodologies has been marked by a shift toward competency-based training and personalized learning plans. Simulators, both physical and virtual, offer trainees the opportunity to practice and refine skills in a controlled setting. Data-driven insights from surgical performance analytics may empower educators to tailor training programs to individual needs, and, therefore, optimize the learning experience.[103] Further, artificial intelligence may also be able to shed insights on trainee performance through the use of real-world patient data. These data, used as a supplement to current assessment modalities, could serve as the ultimate arbiter of trainee competence in patient care.

Another alternative to real-time assessment in the physical training environment is video review of surgical technique based on review of actual operations.[104] In recent years, this approach to competence assessment has gained popularity, especially in minimally invasive procedures where recording is feasible. Evidence suggests that crowdsourcing can be used to accurately assess surgeon competence, and, in the future, artificial intelligence may be able to perform this assessment independently. Some surgical boards, like Urology, are already considering the use of video review as a component of assessment for certification.[105]

Technology will help to propel surgical training forward with immersive simulations, personalized feedback, and global collaboration. To date these efforts have been contained to focusing on individual learner growth and development, primarily during undergraduate and graduate medical education. At some point, focusing the lens on the system to refine the scope of the field and tailor the programmatic requirements to match the needs of the population will accelerate the path to progress. Further, the state of technology today can only serve as a supplement to the role that humans play in surgical education, and, as such, extending efforts to focus on deliberate practice as a means to competence may be the way to push the field forward and create an efficient learning process.

CONTINUOUS PROFESSIONAL DEVELOPMENT AND LIFELONG LEARNING

Surgery, a field defined by meticulous attention to detail, continuous advancement, and a responsibility to serve the public, demands a lifelong commitment to learning and adaptation. All practicing surgeons have an obligation to remain at the forefront of medical knowledge and surgical technique. Continuing medical education (CME) programs provide opportunities for ongoing learning for practicing surgeons and Maintenance of Certification (MOC) programs are designed to ensure acceptable compliance with this professional requirement.

Although formal surgical training takes place in medical school and the period known as graduate medical education, the majority of a surgeon's professional life is spent in practice. Advances in medical science, surgical technology, and clinical guidelines occur at a rapid pace with a doubling of medical knowledge approximately every 73 days.[106] As such, ongoing education is critical to the safe and reliable practice of surgery. To facilitate and track the professional development of practicing surgeons, the medical community has established structured programs for CME.

CME programs encompass a wide range of educational activities, including conferences, workshops, online courses, and medical journal reading. CME activities are designed to cover clinical updates, emerging therapies, patient safety, medical ethics, and more. For instance, the ACS offers CME activities tailored to surgical practice.[107] These programs allow surgeons to earn credits while staying current with advances in the field. By participating in these activities, surgeons fulfill regulatory and licensing requirements while expanding their knowledge base.

MOC programs take the commitment to ongoing learning a step further. These programs require surgeons to demonstrate their competence periodically through assessments such as self-assessment modules and performance evaluations in practice. The ABS oversees a MOC program that encompasses four components: medical knowledge, lifelong learning and self-assessment, practice performance assessment, and communication skills.[108] Surgeons are required to complete these four components to maintain their board certification. MOC ensures that surgeons remain actively engaged in meaningful learning, self-assessment, and practice improvement throughout their careers.

Lifelong learning is an integral part of surgical practice. Successful strategies for the integration of ongoing learning into daily surgical regimes include (1) routine reading and journal review, (2) collaboration with colleagues, (3) interdisciplinary collaboration, (4) self-assessment via reflection and the use of formal assessment tools, and (5) commitment to the incorporation of learning into practice to stay current. In the dynamic field of surgery, adoption of these practices is critical to the fulfillment of our professional responsibilities.

CONCLUSIONS

Surgical education provides a foundation for the safe and effective delivery of surgical care to the population. Advances in competency-based surgical education have the potential to further improve surgical quality and blunt many of the adverse effects of training on surgical trainees and faculty. As the workforce continues to diversify, additional efforts are needed to ensure an unbiased assessment process to optimize the effectiveness of feedback and enable benchmarking of performance. Efforts to optimize training paradigms to match the needs of the population and the evolution of technology are ongoing with major accomplishments in specialties like cardiothoracic surgery. Investments in the standardization of CME may help to ensure evidence-based, uniform care across settings and populations.

  - Wearable Technology
  - Future Directions

Conclusion

INTRODUCTION

Surgical simulation is a relatively new idea that gained popularity in the 1990s with the introduction of minimally invasive surgery and the need to teach laparoscopic intracorporeal suturing to surgeons who trained before the laparoscopic era. In addition to training for specific skills, simulation could also teach procedures, operations, and teamwork. For 25 years, many surgeon educators argued whether simulation was a valuable use of resources, time, and personnel and whether it was cost-effective when compared with cadavers, live animal surgery, and even patients. Surgeons were initially skeptical about plastic mannequins, foam organs, mock operating rooms (ORs), and virtual reality (VR) OR displays. Many of the initial naysayers today embrace simulators and simulation. Simulation is even finding its way into mainline surgery textbooks such as Sabiston's 21st and 22nd editions.

Purpose and Goals

In this chapter we provide an overview of the evolution of surgical simulation and several of the events, research studies, and national curricula that have impacted how we teach and learn surgery. As we embraced simulation, we began to rethink what we are teaching students, residents, and OR teams. To be more effective, we incorporated best practices that include adult learning theories, feedback, and formal debriefing. Slowly the adage of "see one, do one, teach one" was replaced by concepts of "perfect practice makes perfect." Simulation provides a safe place to learn skills, practice error recovery, and master technical and nontechnical skills.

Simulation Background and History

Although the aviation industry embraced simulation for training pilots, surgeons were slow to adopt simulation training in the 1990s. When offered the opportunity to practice on a video trainer, surgical trainees might mutter, "Aren't my patients good enough to practice on?" and "What's the proof that simulation works?" In addition to pushback from naysayers, operations were technically much more complicated to simulate than flight. In 1995, surgeons approached the airlines industry, who thought a realistic simulation for surgery like pilots used for learning to fly planes was impossible. Surgeons initially shied away from simulators and instead looked to using models and video trainers and demonstrating that practicing tasks in a skills lab improved trainees' operative performances doing a laparoscopic cholecystectomy and laparoscopic hernia.[1,2]

Over the next decade medical simulation centers sought to teach procedures such as central line placement and laparoscopic cholangiography. Commercially, simulators came to market with VR simulators to teach common operations including laparoscopic cholecystectomy, fundoplication, gastric bypass, and endoscopy. The National Institutes of Health also invested in the development of VR simulation for surgical training.[3–6]

Dr. Ara Darzi was the first surgeon to create a simulated bleeding femoral artery scenario and measure technical and nontechnical skills of the OR team as they addressed the crisis.[7] In so doing, surgeons moved from tasks, procedures, and operations to using simulation to address team behaviors.[8] Controlled Risk Insurance of Vermont, Inc. Risk Management Foundation (CRICO/RMF) and the Harvard Medical School teaching hospitals required surgeons, anesthesiologists, and nurses to participate in OR team training and debriefing. This training was done in simulation centers and in vivo in actual ORs.[9] Scenarios taught the use of checklists, closed-loop communication, and speaking up and varied from uncontrolled hemorrhage to management of a lost sponge. CRICO/RMF believed team training improved team communication and likely decreased malpractice claims to ultimately improve patient safety.

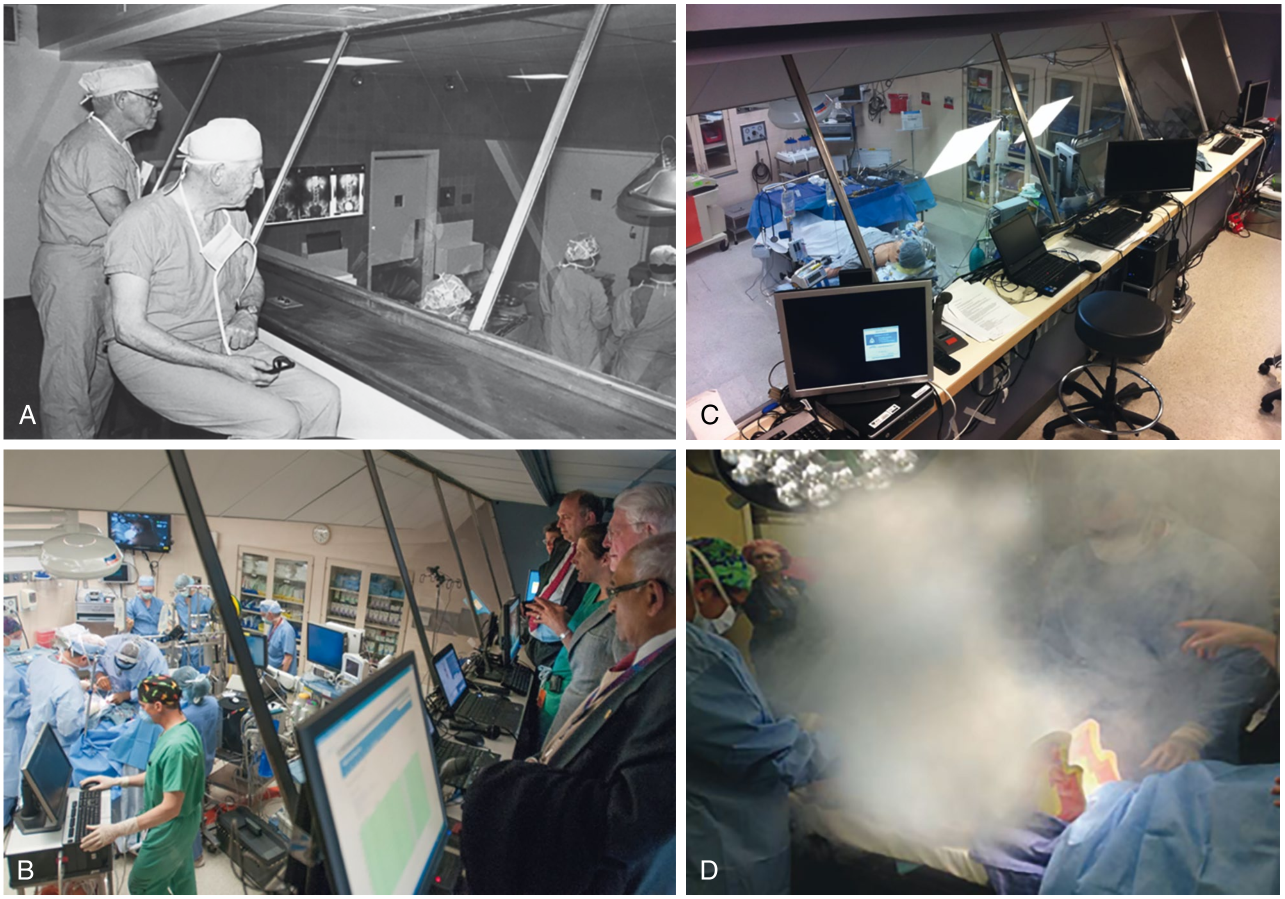

FIGURE 2.1 (A) Photos of old 1960 observation deck. (B) Overhead control room of in situ simulation setup at Massachusetts General Hospital. (C) Opening of the observation deck on April 25, 2013. (D) In situ simulation with fire in the operating room using a low-fidelity mannequin. (B, Courtesy James Gordon. C, Courtesy Inger Aliason.)

Surgical simulation was recognized nationally when the American College of Surgeons (ACS) created the Accreditation of Education Institutes (AEI) with the purpose to form a consortium of accredited simulation centers in 2005. Endorsement of simulation by the ACS marked a transition from simulation being a value added to an expectation for training surgeons. Today there are over 100 accredited AEIs globally. Basic skills labs have evolved into comprehensive simulation centers with dedicated staff (Fig. 2.1).

The culture of simulation has given rise to the use of many new technologies, such as three-dimensional (3D) printing for teaching and practicing,[10] video-based assessments (VBAs) replacing direct observation, and artificial intelligence (AI) readily available for skills coaching, whereas VR ORs with multiple avatars allow operative teams to practice solving complex problems during crises,[11] and gamification keeps learners engaged.[12]

EFFECTIVE USES OF SIMULATION FOR TRAINING

High-fidelity simulation can be a complex educational endeavor requiring careful coordination of institutional facilities, equipment, instructors, learners, simulation technicians, and time. Simulation centers traditionally feature several teaching strategies including static model task trainers, VR endoscopic/laparoscopic/robotic simulators, standardized actors (patients/students/healthcare team members or providers), and mannequin-based scenarios. These strategies can be combined to simulate complex healthcare environments or moved into real healthcare workspaces to create in situ simulation learning and teaching opportunities. Advantages of in situ simulation include the highest degree of realism as well as improved utility for both learners and instructors with the ability to train larger groups of learners and detect any latent system issues. The disadvantages of in situ simulation include logistical challenges of finding unused clinical workspaces as well as the need for detailed policies and procedures to prevent any leakage of simulated materials into patient care areas.[13] Numerous studies have demonstrated that simulation that facilitates effective learning should include careful presimulation planning, constructive learner feedback, and deliberate postsimulation debriefing processes.

In terms of presimulation planning, there are several important conditions. The first condition is that the simulator or simulation should have undergone a validation process for the learning task(s) or knowledge being taught (please see previous paragraph for a description of accumulating validity evidence for a simulator or simulation). Next, the simulation should have specific goals and outcomes that learners are expected to achieve during or after the session. This condition is especially important with inter- or intraprofessional simulations when an instructor may have multiple distinct types of learners who each have different learning goals and expectations. Clearly outlining the expected goals and outcomes also allows each learner to actively engage with the simulation material and personalize/focus their learning needs through multiple learning strategies including, but not limited to, asynchronous presimulation materials, group didactics, and postsimulation debriefs. Another important condition of effective simulation is that the simulation case or scenario should be carefully controlled and revised to both capture the actual clinical variations and feature a range of difficulty levels for each learner group(s). This condition means that the simulation case should likely feature some sort of repetition within the same group of learners so that that they can try different clinical strategies and evaluate their outcomes. Finally, one of the last, but possibly most important, conditions for simulation to facilitate effective learning is that the simulation must be integrated into the larger curricula for all learners. In other words, the simulator or simulation should not be seen as an extra or unnecessary component of learning, but rather as an essential supplement for learners to understand how the material fits into the clinical diagnostic or management pathways that ultimately improve patient care.[14]

Once all the conditions for effective simulation have been met, there must be some sort of deliberate process to help learners understand their performance in the context of other learners and what is the desired performance to deliver correct patient care (i.e., feedback). Feedback can be defined as the process of providing knowledge to a learner about their performance during a particular observed activity so that they will use that knowledge to improve their future performance in similar activities. Although this definition seems straightforward, it highlights a complex activity that must be practiced by both the learner in terms of how to receive constructive feedback and the teacher in terms of how to give effective feedback. Specifically, feedback allows the learner to self-monitor their knowledge and skill acquisition progress but may come into conflict with the learner's self-image of themselves in their professional roles or personal values. This conflict necessitates the need for feedback to be given on a regular basis as opposed to isolated events so that learners understand the purpose and value of constructive feedback. The feedback process must also be layered with formative and summative learner assessments so that feedback data are given to the learner from multiple sources. It is important to realize that all feedback methods must end with a learner performance improvement plan. This plan must contain specific activities the learner can do to improve their future knowledge or skills when confronted with a similar situation.

Lastly, effective simulation should include a deliberate postsimulation debrief session. These sessions could include both a review of the goals and learning objectives of the simulation session and a discussion regarding the learners' performance during the simulation and how that may influence future clinical practice. Debriefing faculty should be comfortable with skills that include postsimulation facilitation, creating psychological safety, and conflict management/resolution.[15] Faculty development in debriefing skills is an essential and often overlooked component of high-quality simulation learning and should specifically address common postsimulation debriefing challenges such as correcting misalignment of faculty and learner goals/objectives, remediating medical errors or mismanagement during the simulation that would result in serious patient harm, and processing strong learner emotions and feelings.[16]

Postsimulation debriefing challenges may be ameliorated or exacerbated through the faculty teaching approaches, which can be either instructor centered or learner centered. Instructor-centered debriefs focus on how the instructor can most efficiently impart knowledge to the learner in a specific and directed learning environment. On the other hand, learner-centered debriefs tend to derive from constructivist learning theories that view the simulation, debrief, and faculty as part of a series of shared experiences that assist the learner in creating new knowledge and understanding about a particular or related topic(s). In general, it is unlikely that only one teaching approach will be best, Faculty should anticipate learner challenges during simulation scenarios so that instructors guide development and practice. Faculty should also try to balance their teaching with time for learner reactions and self-assessment, overall faculty experience with exploring what happened during the simulation and closing any obvious performance gaps, and respect for the local culture.[17]

In summary, simulation leads to effective learning when it contains careful presimulation planning, constructive learner feedback, and a deliberate postsimulation debriefing process. These components can be included in any range of simulation activities but are critical for any interprofessional or high-fidelity simulation scenario. The rest of this chapter will detail other important components of using simulation to improve learner performance.

NATIONAL SIMULATION-BASED CURRICULA

The Fundamentals of Laparoscopy Story

The Fundamentals of Laparoscopy (FLS) was the first nationally validated surgical simulation curricula. It was developed in 1995 by the Society of American Gastrointestinal and Endoscopic Surgeons (SAGES) to ensure that all surgeons had the basic laparoscopic skills to be safe surgeons. FLS examination was a multiple-choice test to assess knowledge of laparoscopy and a series of technical skills. The curriculum was managed and endorsed by SAGES and the ACS. Today, FLS is required by the American Board of Surgery (ABS) as a prerequisite for taking the General Surgery and Obstetrics and Gynecology Board examinations.

Other Standardized Curricula

After FLS, SAGES developed the Fundamentals of Endoscopic Surgery (FES) and the Fundamental Use of Surgical Energy (FUSE). The FES curricula assess endoscopic knowledge and skill. The endoscopic simulator employs VR and uses a commercial simulator for testing. Like FLS, FES is also required as a prerequisite by the ABS before taking the General Surgery and Obstetrics and Gynecology Board examinations.

FUSE is the third SAGES Fundamentals course. It assesses a surgeon's knowledge of energy and devices in the OR. The FUSE examination does not require simulators; however, several VR simulators have been developed to teach principles and radiofrequency energy[18,19] and management of an OR fire.[20]

SAGES has developed a program to foster deliberate lifelong learning[21] called the SAGES Masters Program. This program integrates FLS, FES, FUSE, and other educational courses such as Essentials, the American Society for Metabolic and Bariatric Surgery (ASMBS), and Safe Chole into pathways of advance study. Learners enroll after fellowship and advance from competency to proficiency to mastery levels. Coaching is an important part of the curriculum as is video assessment.

The Division of Education of the ACS has developed formal simulation curricula for medical students and residents. ACS-ASE Skills-Based Curriculum for Medical Students spans years 1 to 3 and is based on a survey of students and clerkship directors.[22] Tasks from https://learning.facs.org/content/acsase-medical-student-simulation-based-surgical-skills-curriculum include skills a medical student should know from digital rectal examination to

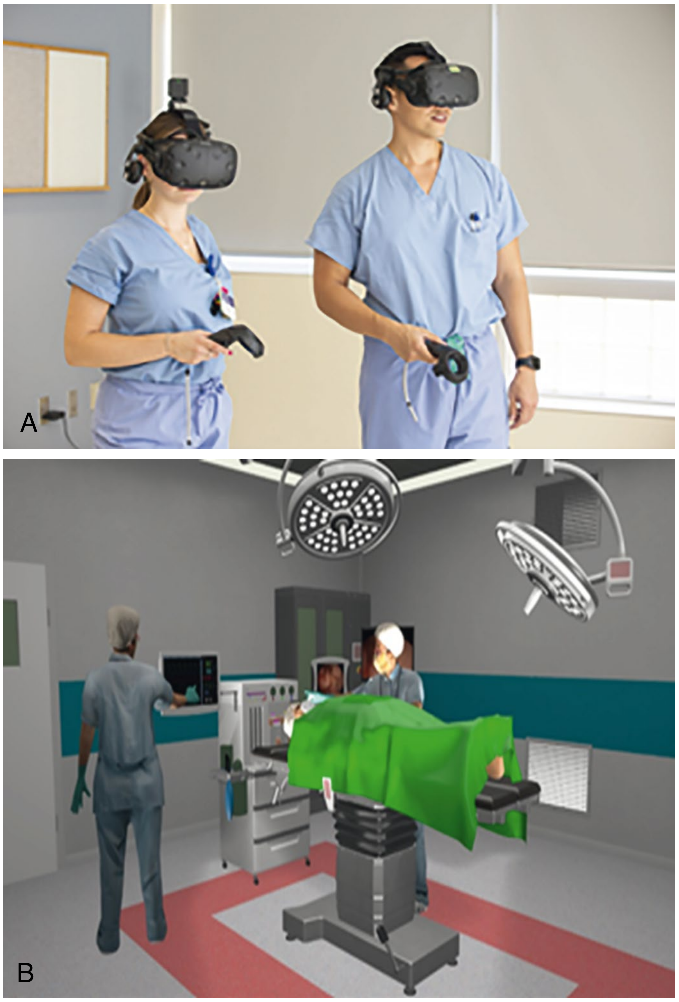

FIGURE 2.2 (A) Live participants wearing virtual reality (VR) headsets and using handheld navigators to experience a virtual operating room. (B) Participant view of the virtual operating world through the VR wearable headset.

IV insertion to basic suturing. Similarly, ACS Association of Program Directors in Surgery (APDS) Resident Simulation Curricula found at https://www.facs.org/for-medical-professionals/education/programs/acsapds-surgery-resident-skills-curriculum/ teaches skills, procedures, operations, and team training. The Integrated National Curriculum in Surgical Education (INCISE) will soon track the learner's engagement and completion of modules leading to a certificate.

Other curricula are being advocated by the industry such as the robotic curricula, which uses robust simulation for robot-performed tasks, and robot-assisted inguinal and ventral hernia (Fig. 2.2).

System-Level Benefits of National Curricula

FLS was required by the ABS of all trainees, but not of surgeons already in practice. However, surgeons in practice may have trained before the introduction of laparoscopy and were self-taught or relied on a weekend course. CRICO/RMF, the malpractice carrier for the Harvard teaching hospitals, worked with surgeons to promote patient safety. CRICO/RMF paid for surgeons to take the FLS examination and offered an incentive of $500 to the department of surgery for each FLS examination successfully passed. Most attending surgeons practiced in the simulation center. Some who failed opted to not have laparoscopy as a hospital privilege. The hospitals ultimately encouraged or required FLS for hospital privileges.[23]

Subsequently, CRICO/RMF supported OR Team Simulation training with multimillion dollar grants so that surgeons, anesthesiologists, and nurses could train together. These are just two examples of how a malpractice carrier can advance technical and nontechnical skills with the goal of improving patient safety.

SIMULATION-BASED ASSESSMENT

As simulation-based training has become best practice in surgical education, interest in skills assessment and associated assessment processes has followed. In surgical education, the assessment of skills is typically divided into two main categories: technical skills and nontechnical skills. Technical skills assessment primarily evaluates proficiency in performing surgical procedures and applies some quantifiable score either to specific actions or steps in a procedure; they may serve as a general measure of manual dexterity, precision, and ability to manipulate surgical instruments. Nontechnical skills assessment is used to evaluate aspects of a surgeon's performance that go beyond technical skills, emphasizing decision-making, communication, and leadership. Most recently a shift to competency-based assessment has driven the development of new tools that measure autonomy in the operative setting. We highlight examples of the most commonly utilized assessment instruments used in surgical education and their benefits and disadvantages (Table 2.1).

Technical Skills

Checklists

Procedure-specific assessment tools (PSATs), most commonly referred to as checklists, generally consist of discrete, stepwise tasks that are required to successfully complete a specified procedure framed within specific start points and end points. Most often scored dichotomously (1 = performed, or 0 = not performed), checklists continue to be most often used as the means to provide formative assessment, delivered for the purpose of providing guidance to developing surgeons during instruction and practice. Their use in the training setting has easily and effectively been used to substantiate direct observations during practice in the simulated setting. The most commonly used checklists are those provided within the ACS/APDS Surgery Resident Skills Curriculum.[24] The benefits of procedure-specific checklists include being relatively easy to develop by surgeon-instructors, and they are perceived as easy to score, given their chronologic ordering of steps; thus, they generally require little rater training before their use. The obvious disadvantage of checklists is their inability to measure and report overarching or "global" surgical skill. Additionally, generalizable use across settings and practices is often limited by the differences in instructor or institutional preferences (e.g., differences in anastomoses methods). Finally, and most importantly, determining rigorous pass/fail standards of checklists also can be a challenge, and the scientific evidence (called *validity evidence*) that would be used to support the use of checklists to assess operative skills is inconsistent. As surgical educators are becoming more aware of checklists' limitations, other types of simulation-based performance assessment tools have been developed, and their validity evidence has been reviewed using updated codified standards.[25]

TABLE 2.1 Commonly Used Assessment Instruments in Surgical Education

NAME	DESCRIPTION	BENEFITS	DISADVANTAGES
Technical Skills Assessment			
Checklists (Procedure-Specific Assessment Tools)			
Asepsis and instrument identification, knot tying, suturing, skin flaps, skin grafts, urethral catheterization, airway management chest tube insertion, central line insertion, surgical biopsy, laparotomy, hand-sewn bowel anastomosis, stapled bowel anastomosis, arterial anastomosis	ACS/ADPS Phase 1 Curriculum[24] 16 tools, 14 of which have stepwise, task-specific checklists. Variable item-length, all scored using 0 (Not Done or Incorrect) and 1 (Done Correctly). Accessible via registration to course	• Easy to develop and use • Can be used for assessment via direct and video-review observation • Adaptable • Supports formative feedback well	• Require direct observation either live or via video review • Difficult to set performance standards unless mastery expected • Validity evidence (reliability) is limited
Global Assessments			
Objective Structured Assessment of Technical Skills (OSATS)[25]	Seven-item tool used to score general surgical performance quality scored using 5-point rating scales with varying anchor language at that represents 1 = low/inadequate, 3 = moderate/adequate, 5 = excellent, above adequate[25]	• Generic language makes it generalizable across surgical procedures, making it very adoptable/adaptable • Validity evidence supports use for low-stakes assessment and in operative setting (bariatrics, colorectal)[27]	• Requires direct observation either live or via video review • Lacks specific feedback on specific steps • Requires pairing with a checklist to provide quality feedback for formative assessment
Global Operative Assessment of Laparoscopic Skills (GOALS)[28]	Adapted from OSATS, a five-item global rating scale used to assess surgical performance quality in laparoscopic setting. Similar scoring rubric as OSATS[25]	• Validity evidence supports the use of it and modified versions in laparoscopic skills training and in operative setting[27]	• Same as OSATS
Global Evaluative Assessment of Robotic Skills (GEARS)[29]	Adapted from GOALS, a six-item global rating scale used to assess robotic surgical performance quality across 5-point ratings, similar to OSATS[25] and GOALS[28]	• Some validity evidence supports the use of it and modified versions in robotic skills training and in operative setting[29,30] • Metrics captured via automated assessment have shown preliminary assessment value[30] • Demonstrated value of crowd-sourcing assessment of surgical performance[30]	• Same as OSATS
Nontechnical Skills Assessment			
Non-Technical Skills for Surgeons (NOTSS)[31]	12-item instrument measures individual surgeon's nontechnical skills across four domains: Situation awareness, Decision-making, Communication and teamwork, and Leadership. These are scored using a 4-point rating scale: 1 (poor) to 4 (good)[31]	• Easy to use assessment that complements performance assessment tools for feedback in training setting • Sufficient evaluation of validity evidence supports its use [32]	• Require direct observation either live or via video review • Rater training may be required to ensure interrater reliability
Non-Technical Skills (NOTECHS II)[33]	16-item instrument measures team's nontechnical skills across five domains: Communication and interaction, Situation awareness and vigilance, Cooperation and team skills, Leadership and management, and Decision-making. These are scored using rating scales (variable, based on application), with the majority using a 4-point system: 1 (poor) to 4 (excellent)[33]	• Sufficient evaluation of validity evidence supports its use to assess teams' skills in operative setting[34]	• Same as NOTSS
Competency-Based Assessment			
Zwisch Scale[35]	A 4-point rating of autonomy[34]	• Can be applied as a response option to checklist, global assessment • Robust validity evidence for use in simulation and operative setting[36]	• Requires direct observation either live or via video review

ACS, American Colleges of Surgeons; *ADPS,* Association of Program Directors in Surgery.

Global Assessments

Global assessment instruments, often referenced as global rating scales, are tools that provide a comprehensive evaluation of a surgeon's overall performance during a surgical procedure. Unlike assessments that focus on specific procedural skills, a global assessment can be applied to a broad range of procedures because it is intended to measure overarching factors related to the surgeon's competence, such as dexterity and ability to handle tissue. We highlight the global assessments most used in simulation, beginning with the Objective Structured Assessment of Technical Skills (OSATS). The OSATS is a seven-item global assessment in which each item, or domain, is scored on a unique 5-point scale and summed.[26] Since its introduction in 1997, OSATS has been applied widely across numerous surgical applications and has been the focus of over 440 studies, including those that have used the OSATS in its entirety or in a modified form (m-OSATS), and it has been viewed synchronously via live direct observation or asynchronously via digital recordings.

Other global operative skills assessment instruments have been developed for more specific applications (Figs. 2.3 and 2.4). For example, for laparoscopic surgery, the Global Operative Assessment of Laparoscopic Skills (GOALS) instrument measures skills across five domains, including (1) depth perception, (2) bimanual dexterity, (3) efficiency, (4) tissue handling, and (5) autonomy. These are all rated on unique 5-point rating scales.[27] With over 100 referenced validation studies, GOALS and modified versions have been validated for a broad range of laparoscopic procedural skills training, with relevance and value in the operative setting. The Global Evaluative Assessment of Robotic Skills (GEARS) adopted the five GOALS domains with the addition of a sixth, "robot control," which has been successfully applied to robotic surgery.[28] GEARS has become the most studied and applied performance assessment tool for robotic surgery[29] with success demonstrated in training applications.[28,30]

Nontechnical Skills

Development of nontechnical skills for surgeons has been recognized as equally important as technical skills in surgical care. A systematic review of 84 articles included 23 different surgery training programs that targeted nontechnical skills.[31] The two most studied training programs that were associated with rigorous assessment were the Non-Technical Skills for Surgeons (NOTSS)[32] and the Oxford Non-Technical Skills (NOTECHS)[33] programs. The 12-item NOTSS assessment instrument was designed to measure individual surgeon's nontechnical skills in the operative setting for the purposes of providing debriefing following a simulated scenario. With aspects that reflect both checklist and global assessments, this easy-to-use instrument has been successfully applied in a variety of specialties, and a systematic review of 12 studies by Jung et al. praised the NOTSS' robust validity evidence to measure individual surgeon's nontechnical skills in the operative setting with reasonable reliability.[34] The NOTECHS scale is an assessment instrument born in the aviation world, and it has become the most commonly adapted tool used to assess nontechnical skills of healthcare professional teams. Modified for use in surgical settings, the latest form consists of five nontechnical domains related to crisis resource management, scored on 4-point scale.[33] Although the primary disadvantage of the NOTECHS tool is that it is founded on the tenuous assumption that a team's performance equals the sum of the individual team members' performances, studies of validity evidence consistently support the tool's use to assess teams' nontechnical skills in the operative setting.[35]

Most of the assessments described have demonstrated their value beyond simulation-based training, with some evidence that supports measuring surgical performance skills in the operative setting. For example, the systematic review by Grüter et al. examined and graded the validity evidence presented by 55 studies of the appropriateness of commonly used surgery performance

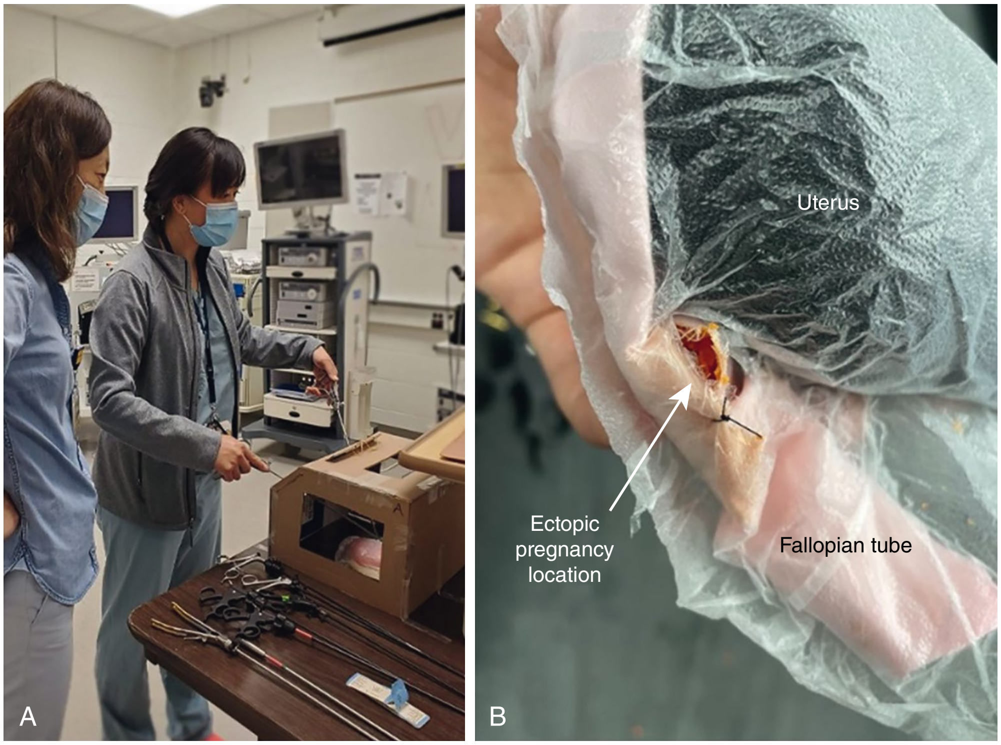

FIGURE 2.3 (A–B) The ALL-SAFE laparoscopic skills training system for use in low- and middle-income countries.

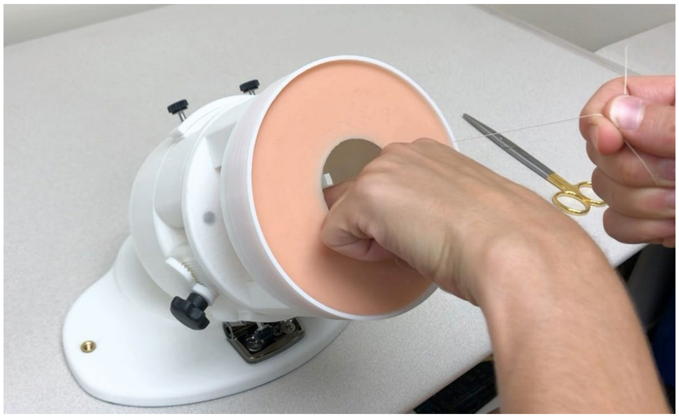

FIGURE 2.4 The Fundamentals of Vaginal Surgery skills training system for obstetrics and gynecology.

assessment tools in the operative setting.[36] Of the studies examined, 11 reported findings that adequately supported the assessment tools' use in the operative setting with measures that directly related to patient outcomes. Although all studies were limited to the fields of colorectal and bariatric surgery, three studies supported the use of global rating scales, and eight supported the use of checklist ("procedure-specific assessment") tools. These findings provided early validity evidence that supports the utilization of commonly used assessment tools to translate performance measures from the simulated surgical field to surgical practice. This area of research is particularly important as surgical educators, hospital leadership, and credentialing bodies are striving to ensure that simulation-based surgical skills are successfully and safely translated to patient care in the operative setting. This opinion is reflected by the ABS and other key surgical education partners as they have shifted from time-based requirements to competency-based requirements.[37] These range from specific entrustable professional activities (EPAs) to broader measures of autonomy, all with the intent to ensure graduating surgical trainees are well prepared for independent practice.

The most widely used measure of the intraoperative trainee, typically a surgery resident, is autonomy. This has been readily accepted and applied in the surgery education setting using the Zwisch scale.[38] Now incorporated into the System for Improving and Measuring Procedural Learning (SIMPL) assessment toolkit (simpl.org), the Zwisch scale is a 4-point rating scale that ranges from 1 (Show and Tell), in which the trainee is watching and learning, to 4 (Supervision Only), in which the trainee is operating autonomously with supervision alone. It can be applied as the response option to any assessment of surgical task or procedure within a checklist or global assessment.[39] The SIMPL assessment toolkit, which also takes operative supervision and case complexity into consideration, has been demonstrated to be an effective tool to track trainee operative performance and autonomy in general surgery and a variety of specialties including cardiothoracic, otolaryngology, pediatric, urology, and vascular surgery. With widespread acceptance as a measure of trainees' autonomy in the OR, the SIMPL toolkit could easily be applied earlier in training, such as in the simulation laboratory, to better support a culture of ongoing formative feedback in the operative setting, which ultimately promotes lifelong learning.

The research that is used to evaluate the quality of surgical skills assessment tools has become more sophisticated since the introduction of OSATS 26 years ago. Earlier validity research was initially wrapped in the language of "face validity," a subjective observation of relevance and value from an expert. Now, contemporary practices that are used to evaluate performance assessments' value and rigor are more aligned with those found in high-stakes medical assessment, such as those used in Board examinations, and include a taxonomy that reflects the updated standards,[25] modern frameworks, and necessary science-based validity evidence. This reflects a rich selection of research methods and psychometric statistical analyses required to support or refute an assessment tool's use to assess a nascent surgeon's skill in the OR (Fig. 2.5).

Recent works in the surgical training arena have demonstrated a shift to focusing on modern methods, which reflects a higher level of rigor when evaluating the quality and value of measures used to assess trainees' surgical skills in the simulated setting.[40,41]

The benefits of increased rigor of simulation-based surgical training and assessment have begun to translate to the operative and clinical settings. In the OR, naïve trainees have demonstrated improvements in robotic operative skill after access to 1 month of a simulation-based training program with defined competency goals.[42] Another multi-institutional study on the impact of simulation-based surgical training goals on over 1000 urology surgical cases indicated that simulation-based training that employed OSATS as the formative assessment led to fewer complications and injuries in the OR.[43] The benefits of simulation-based assessments have been demonstrated in the clinical setting as well. A simple half-hour, hands-on experience in which primary care residents practiced examining simulated newborns for developmental hip dysplasia with formative assessment and guided feedback from an orthopedic surgeon instructor resulted in residents clinically diagnosing over 1000 newborns. This was associated with higher diagnostic agreement with hip ultrasounds than with primary care physicians (Fig. 2.6).[44]

PROFICIENCY-BASED TRAINING AND LEARNING TRANSFER

As mentioned earlier, adopting simulation into surgical education has resulted in surgeons developing skills and gaining a much deeper awareness of established learning theories. Although early studies documented the educational benefit of simulation-based training, the training protocols were crude by today's standards. For example, in the first study that documented the transferability of laparoscopic skills from the simulation environment to the actual OR using live patients, the surgery residents were required to train for 5 hours on box-trainer exercises.[1] Although this may sound reasonable, such protocols failed to maximally optimize performance because they lacked the foundational scientific principles required for effective psychomotor learning, intraoperative decision-making, or surgical anatomy.

Anders Ericsson, PhD, was a well-cited psychologist who dedicated his entire career to investigating how individuals develop expertise. Ericsson established the concept of deliberate practice, which involves "the identification of areas for improvement by reflection on performance, followed by intentional adjustments in approach and evaluation of the resultant impact."[45–47] His research demonstrated that the individuals who achieve the maximum level of skill are actively involved in the process of deliberate practice over an accumulated practice time of at least 10,000 hours. Ericsson proposed that through this process the learner continually pushes themselves to improve gradually and continually. Successful improvement requires three conditions for proper

	Test Content	Internal Structure	Response Process	Consequences of Testing
Research Question	What is relationship between training program's learning objectives and the intended content of instrument?	Do the instrument's items work together to consistently measure expected performance changes for everyone?	Are the instrument's use patterns (scoring) well-aligned with the decision patterns?	What are intended and unintended outcomes that result from test reporting?
Evidence	Transparency of development, review process & foundational frameworks	Test of whole instrument's and its items' reliability to measure performance	Test of item-level and whole-test interactions	Defining performance standards and actions taken following the reporting of test results
Example	Written description of process used to determine what steps were critical in performance checklist[31,34]	Statistical analyses to evaluate if performance changes are measurable and agreed upon by judges[28,29,32,33,39]	Analyses of correlation of ultimate decision-making patterns with the performance patterns of the learners and the scoring patterns of the judges? Analyses of scoring differences to evaluate possible unexpected use (bias) across learners, judges[33]	Identification of performance score thresholds and actions if unmet by learner[41]

FIGURE 2.7 A stepwise progression of proficiency-based training. *Performance assessment metrics must be supported by validity evidence.

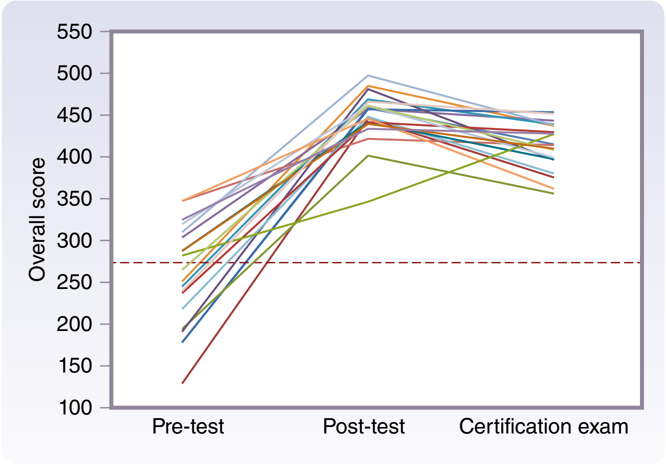

FIGURE 2.8 Performance of postgraduate year 4 to 5 residents (n = 20) who took the Fundamentals of Laparoscopy (FLS) certification examination. The overall score (y-axis) at each testing interval represents performance for all five FLS tasks. Each *solid line* represents an individual resident, and the *dashed horizontal line* represents the minimum passing score (≥270). All residents underwent proficiency-based training between pretest and posttest. Skill retention at 2 years (between posttest and certification examination) was 92%, and all residents passed the FLS examination. (Reproduced with permission from Mashaud LB, Castellvi AO, Hollett LA, et al. Two-year skill retention and certification exam performance after fundamentals of laparoscopic skills training and proficiency maintenance. *Surgery.* 2010;148[2]:194-201.)

execution of deliberate practice to be met. Participants (1) are instructed about specific aspects of performance for a predetermined and well-defined task; (2) obtain detailed, immediate feedback on their performance; and (3) have many opportunities to improve their performance gradually by performing the same or similar tasks repeatedly.

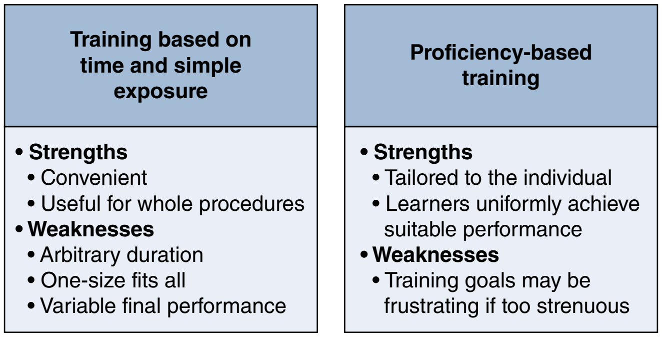
Fortunately, the field of simulation embraced these principles, and significant advancements were made by establishing proficiency-based curricula (Fig. 2.7). The first study to use this paradigm was known as the "VR to OR" study. This study documented six times fewer errors during laparoscopic cholecystectomies performed on actual patients after surgery residents completed simulation-based training.[48] Importantly, this study required the learners to practice until predefined expert levels were reached on the VR simulator. As a result, the time it took for learners to complete the training varied from 3 to 8 hours. Thus, instead of mandating an arbitrary, predetermined number of hours or repetitions, this study introduced the concept that training should be tailored to the individual and that the focus should be on achieving a uniformly high level of performance. Indeed, the rate of skill acquisition may vary considerably, even among learners at a similar level. For example, the FLS proficiency-based curriculum has been in widespread use since it was first published in 2007.[49] An initial study documented that complete novices (medical students) started with a wide variety of baseline skill levels and that training time varied considerably (from 6–14 hours) for the learners to reach proficiency on all five tasks.[50] After proficiency-based training, the learners had much less performance variability, and all achieved a high level of performance that surpassed the minimum passing score for the FLS certification examination. A follow-up study documented similar learning curves and educational benefit for surgery residents who completed the FLS proficiency-based curriculum (Fig. 2.8).[51] This study also documented 92% skill retention at 2 years for postgraduate year (PGY) 4 to 5 residents who participated in ongoing proficiency-based training for laparoscopic suturing; this protocol proved effective in decreasing skill decay for complex skills after initial training.

Validity evidence that supports the metrics used to assess a particular learner's performance is critical to ensure the value of proficiency-based curricula. Traditional studies have established expert-derived performance levels through a series of investigations. First, experts known to have the specific skills relevant to the simulated tasks are recruited to perform consecutive repetitions of each task. Most commonly, outliers are usually defined (for example, those >2 standard deviations [SD] beyond the mean) and excluded, with the trimmed mean being used to represent the expected expert performance. Next, the performance data from nonexpert learners of various levels are also collected. If the performance between known groups of varying levels of expertise is determined to be significantly different, then sufficient evidence exists to justify the use of expert performance levels as a training goal. If such evidence-based data are not available, then using performance scores as a training end point within a proficiency-based curriculum is not justified. For example, a commercially available simulator may generate automated metrics, but without validity evidence to support their use, such metrics may not accurately assess performance, so using them as training goals may be inappropriate.

For curricula that use performance standards formed by validity evidence, the expert level often is “softened” by 1 or 2 SD, depending on the learner level, to limit frustration that may be associated with overly ambitious proficiency levels and to allow for more gradual development of expertise over time. Additionally, many protocols stipulate that the learner must achieve an established proficiency level on two consecutive attempts to verify that the learner is at the desired skill level. To reinforce skill acquisition further, some protocols will also require an arbitrary number of repetitions at or beyond the proficiency level once initial proficiency has been achieved. For example, the FLS curriculum requires that the proficiency level for intracorporeal knot tying must be met on two consecutive repetitions followed by 10 additional nonconsecutive repetitions during the initial phase of training.

Over the past two decades, the previously mentioned training theories and concepts have been widely implemented within surgical simulation. Although performance thresholds may be appropriately established for any type of simulation, proficiency-based training is particularly well suited for task training. Often a protocol may be followed that introduces a set of tasks to the learner during an initial orientation session; this series of events ensures that the learner is familiar with the tasks, and it also facilitates a proctored baseline assessment. Then the learner can self-practice until proficiency is reached. Often this phase of self-assessment is done with the learner using available resources like video tutorials, which show correct task performance, tips and tricks, and errors to avoid. Alternatively, learners may participate in additional proctored coaching sessions when resources are available. Finally, a proctored posttest is completed to facilitate a final assessment; this ensures that a suitable level of performance has been achieved and enables an opportunity to offer remediation if needed.

This framework for proficiency-based curricula is beneficial in several ways, especially compared with traditional time or exposure-based curricula (Fig. 2.9). First, the learners are motivated to reach a known level of expertise. Second, the effectiveness of the educational experience is maximized. Practice is tailored to the individual, allowing learners to take as much time as needed to master the assigned skills. Ultimately, learners are expected to achieve a suitable level of performance, and there is usually very little variability in performance after training. Third, the learning process is efficient. Learners who master a skill rapidly can move on to other pursuits and do not waste time in unnecessary practice. Similarly, many curricula rely heavily on self-directed practice rather than mentored sessions, such that personnel resources are minimized. Numerous examples of such curricula have been described and successfully implemented for open, laparoscopic, robotic, and endoscopic skills (Table 2.2).[50–57]



Training based on time and simple exposure	Proficiency-based training
• **Strengths** • Convenient • Useful for whole procedures • **Weaknesses** • Arbitrary duration • One-size fits all • Variable final performance	• **Strengths** • Tailored to the individual • Learners uniformly achieve suitable performance • **Weaknesses** • Training goals may be frustrating if too strenuous

FIGURE 2.9 Strengths and weaknesses of traditional and proficiency-based training curricula.

For proficiency-based curricula to be successful, several aspects are important (Table 2.3). Sufficient resources must be available to host the training activity. Equipment may include commercially available simulators or other models as well as consumable materials like suture. Sufficient personnel must be available to administer the activity, including scheduling, communication, and tracking learner completion. Content experts may also be needed to support instruction of the various portions and provide feedback. The curriculum must be structured, as described previously, and include baseline assessment, a protocol for proficiency-based training, and final assessment. There must be a mechanism to ensure that proficiency has been reached, such as verification by a proctor. Distributed practice is ideal for skill acquisition because learner fatigue is avoided by limiting training sessions to reasonable durations (usually a maximum of 1–2 hours per day) compared with mass practice sessions of longer durations. Time between sessions fosters consolidation, which is the mental process whereby the learner internalizes the cognitive aspects of how to best perform the task. Leadership support for the curriculum is critical, such that training is viewed as a valuable component of resident education, which is mandatory. For example, in residency programs, complete commitment of the chairperson and program director to provide protected time designated for required simulation-based curricula promotes the culture of ongoing learning and motivates residents to attend sessions and complete the prescribed training. Further, this culture helps to define which residents have protected time, and faculty are expected to excuse these residents from clinical duties to attend simulation activities. If not supported, these curricula risk becoming viewed as optional, leading to learners not completing the training, and the educational benefit is lost.

Integrating proficiency-based curricula into surgery residencies markedly enhances the educational process. Residents uniformly develop fundamental skills in a safe learning environment before using them in the clinical environment. During actual operations, residents do not focus on the development of basic skills because they have already been mastered. Instead, they have sufficient attention resource capacity to learn the nuances of operative strategies like how to identify the correct tissue plane, how to perform a specific dissection, and how to optimize completion of a specific operative step. Residents can listen to feedback provided by their mentor and internalize concepts more deeply. Thus, simulation pretraining augments the amount of learning that can take place during actual clinical operations.

Importantly, proficiency-based training has been clearly linked with not only improved surgeon performance, but also improved clinical outcomes and patient safety. In 2015, Griswold-Theodorson et al. performed a literature review using a translational science model for simulation-based mastery learning (SBML).[58] This group defined the goal of SBML as ensuring that all learners “reach competency standards beyond proficiency levels with little

TABLE 2.2 Examples of Proficiency-Based Task Training Curricula in Surgery

CONTENT DOMAIN	CURRICULUM	TARGETED LEARNERS	TIME TO PROFICIENCY[a]	CITATION
Open skills	Basic suturing and knot tying	Senior students and junior residents	12.7 ± 5.3 hours (range, 6.9–37.1) for PGY1	[53]
	Intermediate suturing and knot tying	Junior residents	3.4 ± 3.8 hours (range, 1–20) for PGY1	[54]
Laparoscopic skills	Fundamentals of Laparoscopic Surgery (FLS)	Junior and intermediate residents	9.7 ± 2.4 hours (range, 6–14) for MS1–M3 (novices)	[51]
	Advanced Training in Laparoscopic Suturing (ATLAS)	Senior residents and fellows	15.9 (13.9–25.8) for MS1 (novices) after FLS training	[55]
Robotic skills	Basic Robotic Curriculum (SimNow VR plus Inanimate Drills)	Junior and intermediate residents	12.1 (10.3–12.9) hours for MS2 (novices)	[56]
Endoscopic skills	Endobubble 1 & 2 (GI Mentor II)	Junior and intermediate residents	Range, 3–4 hours for PGY1–4	[57]
	Fundamentals of Endoscopic Surgery Preparation (Trus Model, Operation Targeting Task, and Kyoto Simulator)	Intermediate and senior residents	2.7 ± 1.3 hours for PGY4–5	[58]

[a] Data are reported as mean ± SD, range, or median [IQR] corresponding to the specified participants groups who participated in the cited studies. *PGY,* Postgraduate year; *VR,* virtual reality.

TABLE 2.3 Important Aspects for Implementing Proficiency-Based Curricula

Resources	Simulation equipment, administrative personnel, and content experts
Structured curriculum	Baseline assessment, training protocol with defined performance goals, and final assessment
Distributed practice	Practice sessions distributed over days/weeks/months
Leadership endorsement	Top-down directives setting expectations for learners and faculty to view curricula as mandatory
Protected learner time	Designated time for learners to be excused from clinical duties

or no variation in outcome." Further, the authors identified seven SBML principles, like many of the proficiency-based principles outlined in this chapter. The translational science model defined the desired consequences of educational interventions in terms of T1, performance in the simulation environment; T2, performance in the clinical environment; T3, patient outcomes; and T4, costs. The review identified 14 articles that reported T2–T4 outcomes *and* included all SBML principles. These studies showed that using SBML can improve patient care processes and outcomes, including procedural success rate, patient discomfort, procedure time, error rate, and healthcare cost. For example, Zendejas et al. documented significantly better surgeon performance, shorter operative times, fewer complications, and fewer overnight stays for laparoscopic inguinal hernia repairs performed by surgery residents who underwent SBML compared with control group residents.[59] Barsuk et al. documented an 85% reduction in central line–associated bloodstream infections (CLABSIs) following SBML for central venous catheter insertion compared with traditional training.[60] Each CLABSI costs $82,000 and was associated with 14 additional hospital days. A return on investment (ROI) analysis showed that central venous catheter insertion SBML resulted in an estimated direct cost savings over $700,000 and an ROI of 7:1.[61] Such data make a compelling case that additional SBML curricula should be developed, and such training practices should be adopted widely.

Additional findings that support proficiency-based training have been recently published. In 2021, Mazzone et al. performed a systematic review and meta-analysis on the impact of proficiency-based simulation training on performance outcomes.[62] Based on 12 randomized studies, the authors documented that compared with standard training, proficiency-based simulation training reduced errors by 60% and procedural time by 15% while increasing the number of correct steps performed by 47%. The largest improvements were found for intraoperative errors on actual patients; thus, a strong association between proficiency-based simulation training and patient safety was established. A 2021 randomized trial by Dean et al. enrolled 49 ophthalmology residents at five institutions and documented improved cataract surgery outcomes following a multimodality simulation-based training protocol.[63] Over a 15-month period, the simulation-trained group had significantly fewer posterior capsule ruptures compared with the standard training group. A 2022 study by Zwart et al. examined adoption of robotic Whipple procedures at seven centers after a standardized training program that included proficiency-based VR and inanimate simulation training, video training, and proctoring.[64] Outcomes were analyzed for the 15 surgeons who completed the training program and subsequently performed 275 robotic Whipple operations. According to complications, mortality, conversions, and hospital stay, the outcomes were acceptable compared with prior reports and demonstrated feasibility and safety of this implementation strategy. In aggregate, the available evidence strongly supports the efficacy of proficiency-based training.

NEW WAYS TO OPTIMIZE PERFORMANCE

Technology-Enhanced Feedback

Feedback is one of the most important requirements for optimizing surgical performance. There are several new technologies and approaches that have great potential to enhance the current workflow for providing feedback to trainees and surgeons in practice. This section reviews some of the modalities that have been used and highlights how these modalities might change the face of surgical education and training through technology-enhanced feedback.

Video-Based Assessment

VBA has emerged as a promising tool in surgery with the futuristic goal of offering real-time, intraoperative decision support.[65]

Live video feeds can capture the surgical process and enable analysis of techniques, instrument handling, and decision-making. Machine learning algorithms have been used to identify patterns and trends, and to develop anatomic and error warning systems. VBA can promote self-directed learning and skill refinement when incorporated into personalized training plans and curricula. Surgical trainees can continuously monitor their progress and identify weaknesses via performance benchmarks from more experienced performers. Practicing surgeons can use VBA for ongoing skill maintenance, for skill enhancement, and for learning new techniques and approaches.

Although VBA holds great promise, challenges such as data security, standardization of assessment metrics, and cost-effectiveness must be addressed.[66] Moreover, hospitals and healthcare organizations wishing to employ VBA as part of their quality assurance protocols to monitor surgical outcomes, reduce errors, and enhance patient safety must first ensure physician trust and value. The tendency toward high-stakes summative judgments and reports must not outweigh the need for formative assessments combined with feedback and coaching. As such, careful consideration of measurement culture and physician wellness is paramount to success for full adoption of VBA.

There are many promising advances that may come to fruition as VBA is further adopted and integrated into the surgical workflow within the simulation laboratory, OR, and other clinical settings. One of the most important opportunities is the curation of a video database of experienced operative performances that can serve as benchmarks for trainees, fellows, and junior faculty. There is also interest in using VBA to objectively assess and communicate best practices. Although some believe that there is a risk of prescriptive, cookie-cutter surgical recommendations, early data are starting to confirm that there is more than one successful approach to an operation.[67]

From an assessment standpoint, competency-based assessments during training and certification processes can benefit from the use of VBA by ensuring that individuals continuously meet established performance standards. The use of VBA in both the simulation laboratory and the live OR will allow for continuity and fluidity of assessment for tracking the learning to competency. As technology continues to advance, VBA will play an increasingly valuable role in shortening the learning curve to competency and mastery. As such, there is great potential for VBA to have an important role in improving surgical outcomes and elevating the standard of care in surgery.

Wearable Technology

Wearable technology is another promising approach that has shown great potential in making significant advances in assessment of surgical skill.[68] A variety of technologies have been used including augmented reality (AR), haptic feedback gloves, functional near-infrared spectroscopy (fNIRS), motion tracking, electroencephalogram (EEG), and other wearables. The common theme of possibilities for these technologies is to enhance feedback and learning through objective measures in the form of data. All these technologies provide unique data visualization, experiences, and tracking that in turn can be used at every stage of the learning curve (Figs. 2.10–2.13). For example, AR headsets worn in the OR have been used to project CT images onto a visible screen to the headset wearer as an anatomic overlay to facilitate surgical planning. In the simulation environment, AR has been used to simulate entire operations and track the learner's technical decision-making and operative knowledge. fNIRS and EEG have been used to track cognitive load and other brain responses during the course of simulated and live operations.[69] Brain waves analyzed during the course of intraoperative decision-making and motor control during manual execution of surgical tasks serve as biomarkers for critical decisions and actions. Wearable eye-tracking technology has been used in a similar way by tracking eye gaze and blink rate, which is indirectly related to intraoperative planning, decision-making, and cognitive processing. This type of information gives insight into surgeon workflows that in turn can be incorporated into meaningful measures for training and surgical skills assessment.[70]

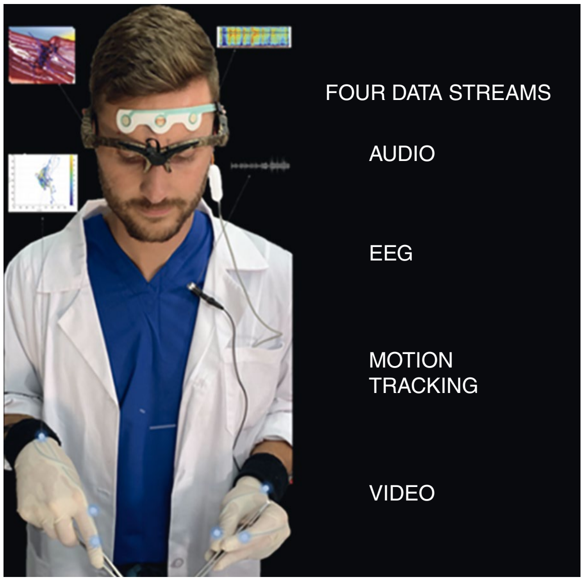


FIGURE 2.10 Wearable technology examples for audio, electroencephalogram *(EEG),* motion tracking, and video.

Motion tracking has been used for over 20 years to digitize the surgical process.[71] Early use focused on motor control and motor actions such as bimanual dexterity, smoothness, and operative efficiency. Recently, motion-tracking sensors have also shown that lack of motion during certain parts of an operation is important and can give insights into other aspects of the surgical workflow such as transitions from one step of an operation to another, brief pauses to gather anatomic insights, and detail such as operative disruptions that take the surgeon's attention away from the operative field.[72]

The integration of wearable technology with simulation-based surgical training has great potential to enable real-time, automated feedback for learners. The value of this process is greatly increased if the feedback is based on established data and performance measures from experienced surgeons because the learners will be able to track where they are on the learning curve to competency and mastery.[73]

Trainees and practicing surgeons who are adopting new technologies and approaches can review their actions, easily identify targeted areas for improvement, and make necessary adjustments in real time. This continuous feedback loop promotes self-directed learning and rapid skill refinement. Moreover, detailed performance data from wearable technology can allow instructors, coaches, and mentors to remotely supervise and guide learners through simulated or live OR cases, thus fostering a more collaborative learning environment based on established performance competencies founded on objective data.

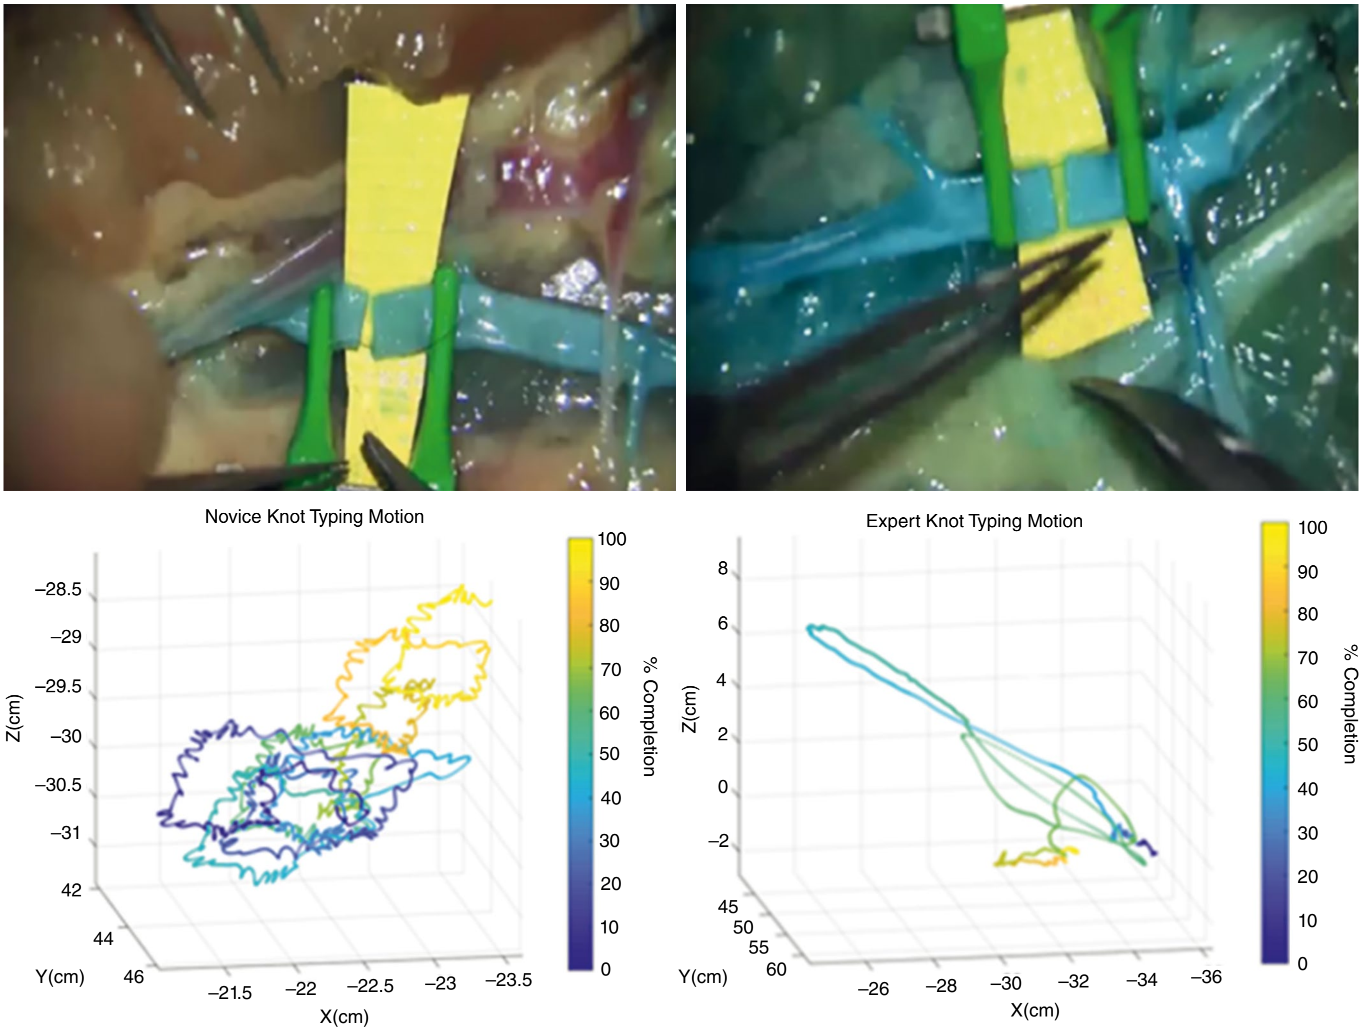

FIGURE 2.11 Motion data comparison between novice and expert surgeons during a microvascular anastomosis.

Although the combination of simulation-based surgical training and wearable technology offers immense promise, challenges persist, including the cost of sophisticated wearables, data privacy concerns, and the need for standardized training protocols. Nonetheless, ongoing research continues to refine these technologies and address these challenges. As wearable technology becomes more accessible and sophisticated, its integration into simulation laboratories and the live OR will become commonplace and change the way future surgeons are trained.

Future Directions

Data-Driven Coaching

With the introduction of VBA and wearable technology, data-driven coaching will become a reality. The overarching goal is to maximize training and assessment for efficient and effective learning. The concept of data-driven coaching takes advantage of wearable technology, which produces data on performance characteristics that are not discernible to the human eye and combines it with the knowledge and natural pattern recognition of a seasoned observer—the coach. This combination will enable precision learning through personalized training, feedback, and assessment. Through continuous monitoring, coaches can offer targeted feedback, ensuring trainees make meaningful progress throughout their surgical education journey. Similarly, data-driven coaching for practicing surgeons learning a new skill or facing reentry into the profession will have a more personalized journey with objective feedback on regaining or achieving mastery.

Artificial Intelligence and Performance Databases

AI algorithms have improved and expanded tremendously over the past 10 years. The computing power of AI has great implications for surgical education, training, and patient outcomes. Current and future uses of AI include predictive analytics relating to surgical outcomes and text generation from natural language models such as ChatGPT (OpenAI, Microsoft Corporation), which is being explored for generation of discharge summaries.[74,75]Another popular use of AI in surgery has been the use of computer vision to analyze surgical video.[76,77] The use of object and phase detection algorithms facilitates efficient review of intraoperative video for analysis of critical events and for generating feedback. Although AI is a powerful tool that facilitates efficiency, one researcher found that AI was less accurate in confirming surgical anatomy during easy cases when surgeons took operative short cuts.[78] Specifically, this occurred when surgeons failed to fully skeletonize the cystic artery and duct during laparoscopic cholecystectomy cases for biliary colic that lacked

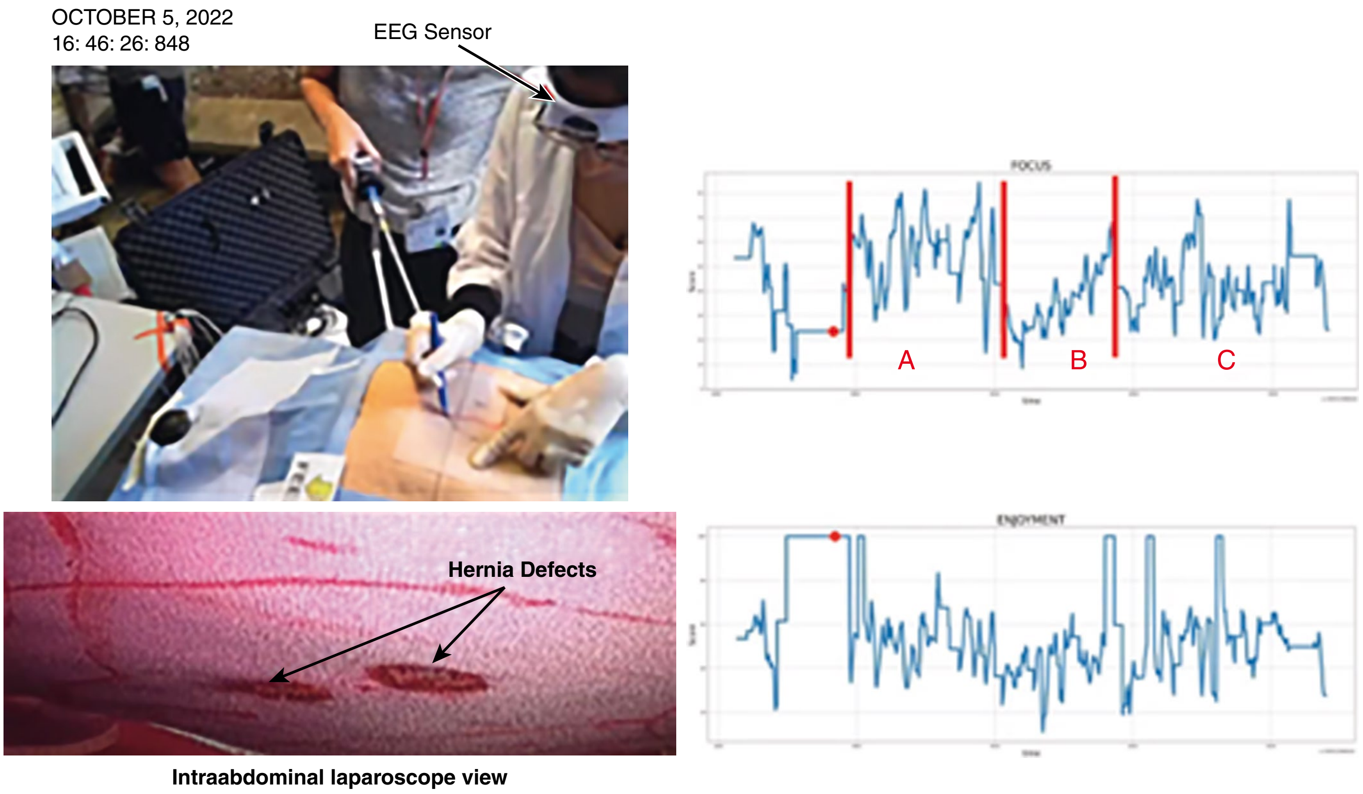

FIGURE 2.12 Real-time electroencephalographic *(EEG)* data during a simulated laparoscopic ventral hernia repair. Three phases are noted. *A,* Mesh prep; *B,* mesh insertion and suture sorting; *C,* securing transfascial sutures.

chronic tissue inflammation or scarring. One known requirement and important limitation of widespread implementation of AI and natural language models (NLMs) is the need for large databases for algorithm training. The number of surgical videos that exist in high-quality, standardized formats are few compared with text-based medical databases such as the electronic health record (EHR). This is the main reason predictive analytic approaches for patient outcomes have surpassed automated, intraoperative decision support tools.[79]

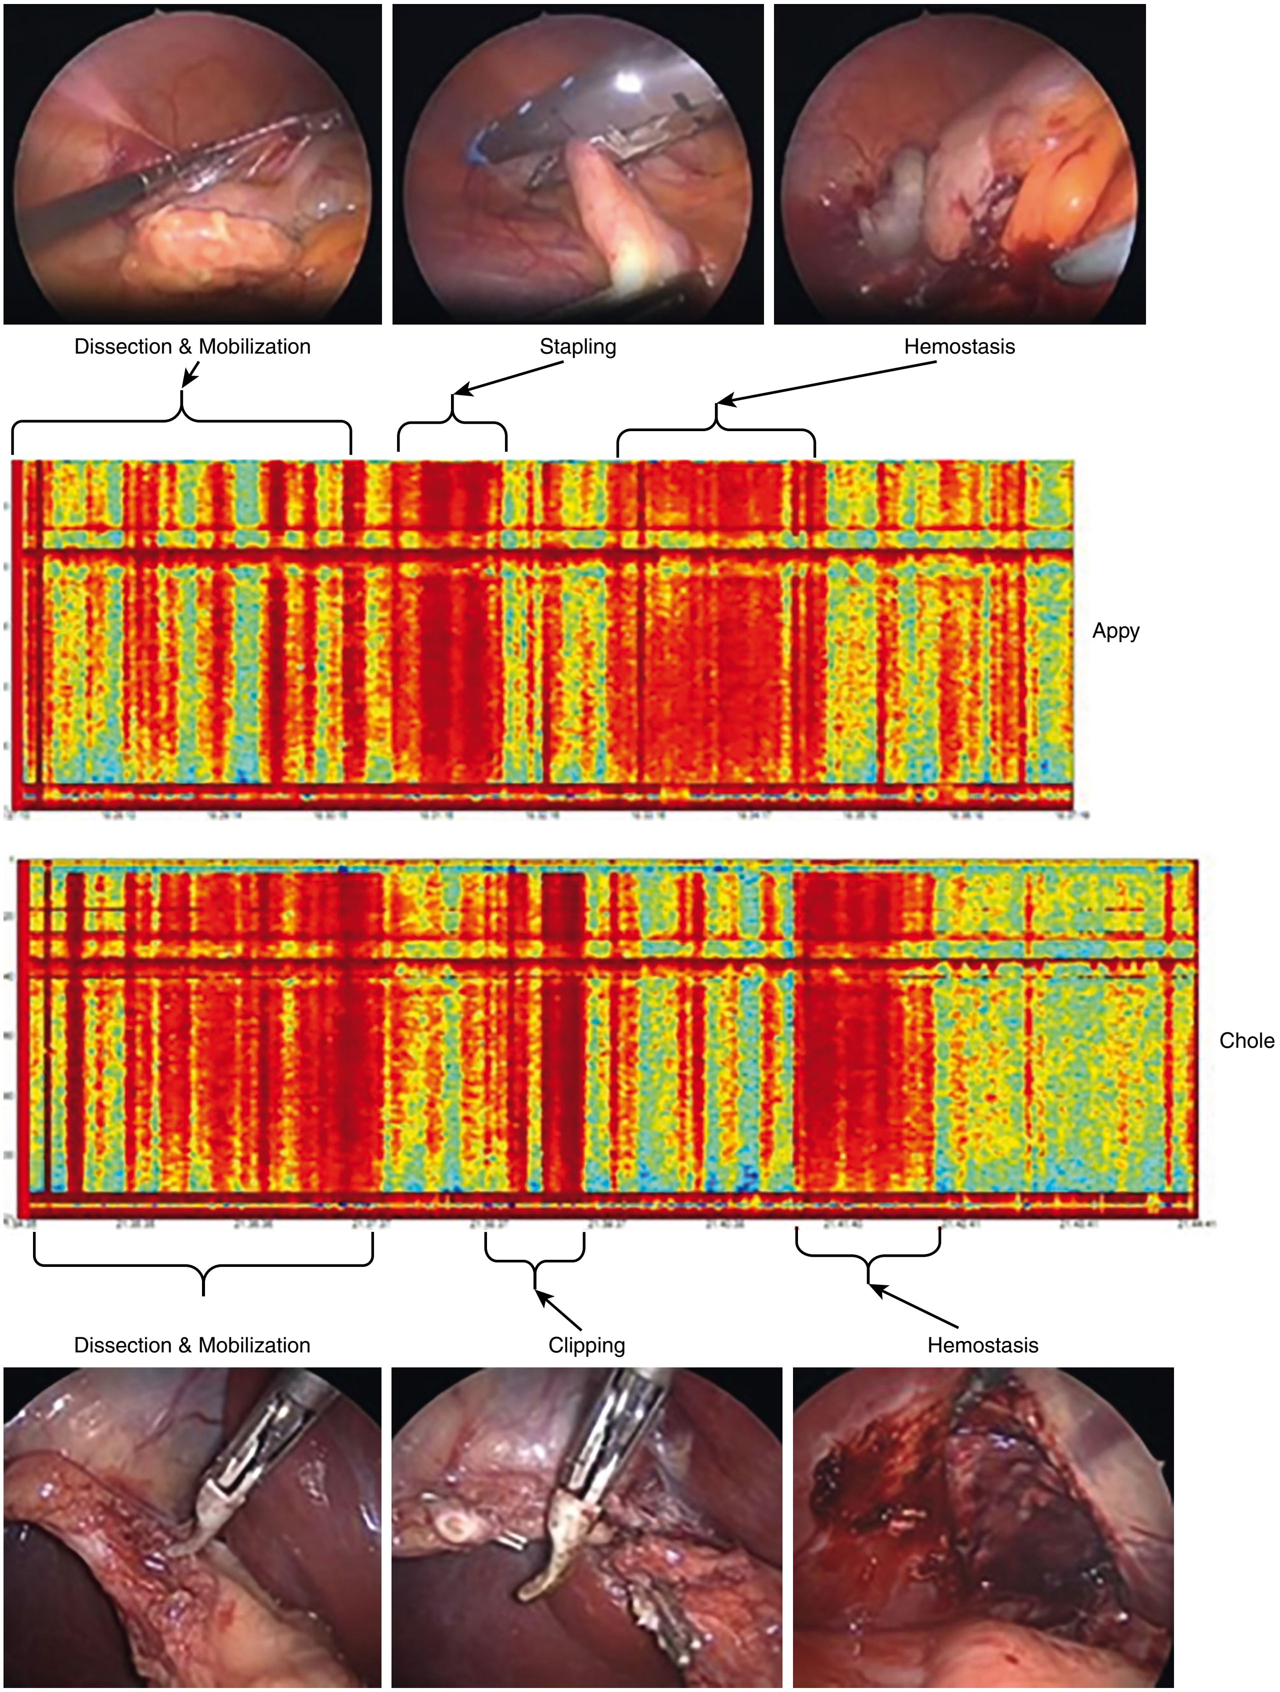
In the future as the surgical community continues to accept and adopt AI, more surgeons will begin to participate in the generation of large databases that will help improve AI's function as an assessment tool. Several surgical organizations are helping surgical communities to procure large video databases that will allow engineers and AI industry groups to further develop AI applications for assessment of surgical skills. The vision and goals of AI use are broad, including empowering surgeons in the preoperative, intraoperative, and postoperative phases of care by analyzing patient data (labs, images, history, medications, etc.) to create comprehensive surgical plans. Moreover, predictive modeling will help assess patient-specific risk factors and help to aid surgeons in selecting suitable interventions and treatment pathways. In summary, the applications of AI range from skill development and patient care to quality assurance with the goal of empowering surgeons, improving patient outcomes, and augmenting the capabilities of healthcare providers and the systems in which they work.

CONCLUSION

This chapter gave a comprehensive review of the background and history of surgical simulation as well as new ways to optimize performance. The ultimate goal of simulation is to allow an opportunity outside of the OR to train residents and surgeons on the safe and efficient delivery of surgical care.

When reviewing the effective uses of simulation-based training, it is notable that the location of the training offers different benefits. Use of tabletop simulators in the simulation lab provides the benefit of enabling group learning for students and residents. Group learning in these settings has historically focused on technical skills such as suturing and laparoscopic skills as well as bedside procedures including intubation and central line insertion. Use of simulation in in situ settings involves placing simulators in a patient care setting and building a more cohesive learning experience with other healthcare providers including nurses, respiratory therapists, and other healthcare team members. Regardless of the setting in which the simulation is used, a notable commonality in the effective use of simulation is feedback and interaction with faculty who can help relate the tasks and skills being learned to the patient care setting.

As simulation-based training has become the best practice in surgical education, assessment of technical and nontechnical skills has become increasingly important. Technical and nontechnical skills have traditionally been assessed using procedure-specific stepwise checklists, and global rating scales have required direct observation and scoring, but there are some issues in this regard.



Dissection & Mobilization
Stapling
Hemostasis
Appy

As surgical approaches have advanced and surgical teams have become more complex, assessment practices for both technical and nontechnical skills have followed with the need to ensure the translation of competency from the simulated setting to the surgical setting. Interest and validation and increased rigor have led to a great deal of research in the area. With promising research that supports the use of assessment to measure trainees' surgical skills, trainees' autonomy in the clinical setting has become more important along with a focus of recent assessment advances. Recent work in surgical training has demonstrated a shift to modern methods that reflect a higher level of rigor when evaluating the quality and value of surgical skills assessment tools used in the simulated and operative settings. This increased rigor has led to benefits that have been seen through improvements to operative outcomes and patient care.

National-based curricula have been created for numerous learner groups and cover various content domains. One of the first national curricula adopted by surgical training programs in the United States was developed by the ACS in collaboration with the Association of Program Directors in Surgery. This simulation-based curricula covered over 10 specific procedures and came with guidelines on how to develop these simulations and how to implement them in the curricula. Also, specific guidelines on how to assess the learners through verification of proficiency were included. Since the development of this program, other curricula have been developed and implemented by individual surgical specialty groups. The most widespread application of these curricula has been to surgery residents with the launch of FLS, FES, and FUSE. Several curricula have been adopted by accrediting organizations such as the ABS.

Simulation-based training has evolved by applying proven learning concepts including deliberate practice. Proficiency-based curricula have proven effective in maximizing skill acquisition and the efficiency of the learning process. Importantly, task-based simulation has resulted in not only improved surgeon performance, but also better patient outcomes, enhanced patient safety, and decreased healthcare costs.

When reviewing new ways to optimize performance for surgical education and training using simulation, several topics were covered including VBA and combining simulation with biologic and motion-tracking technologies and ending with the description of the future of training and assessment. Due to the wide availability of video in AI and computer-based learning, data-driven coaching and real-time feedback are in our near future. As technologies evolve, so will our understanding of how best to train surgical residents and provide them with the timely feedback that they seek to advance their knowledge base and shorten the learning curve. One of the most crucial factors that needs to be addressed in achieving these goals in the future relates to the acquisition of surgical performance data from experienced clinicians. Performance databases are critical to technology advancement and providing real-time feedback for residents and surgeons learning new skills.

In summary, surgical simulation is now a mainstay in surgical education along the entire continuum from residency training through continuing professional development. New ways to ensure effective training and optimized performance will continue to be developed; however, there are specific strategies including proficiency-based training, objective performance assessment, and immediate feedback that have been implemented along the way that will forever serve as a framework of excellence when implementing this technology.

Summary

AMERICAN BOARD OF SURGERY MISSION STATEMENT

The American Board of Surgery (ABS) serves patients, society, and the specialty of surgery by providing leadership in surgical education and practice. The ABS ensures excellence through:

- Building a diverse, equitable, and inclusive culture
- Rigorous evaluation and assessment
- Promoting the highest standards for professionalism, lifelong learning, and continuous certification of surgeons in practice

INTRODUCTION/BACKGROUND/HISTORY

Surgical residency training in the United States is largely based on the German training model of the late 1800s, which was first implemented at Johns Hopkins by William Stewart Halstead. The program at that time was considered to be based on competency as the residents served variable amounts of time in training until they were deemed competent.[1] The downside of this approach is that in 33 years with Halstead as chair at Johns Hopkins, only 17 residents graduated from the program. George Heuer, one of Halstead's graduates, arrived at the University of Cincinnati in 1922 and started a training program with similar training principles but more opportunity for advancement and graduation, leading the transition from the "pyramidal" program in which he was trained to a more "rectangular" program in which every resident who entered could graduate. He subsequently moved to Cornell University and established a similar training program.[2] However, in that era, these programs represented an elite minority of the surgical residency programs such that the graduates of surgical residencies had a wide variety of skills and clinical abilities. Ultimately, this led to the founding of the ABS in 1937. At its inception, the ABS based its lifelong board certification on membership in founding surgical societies or rank of at least associate professor at an approved United States or Canadian Medical School. Physicians who had limited their practice to surgery for at least 15 years were also eligible to petition for certification without examination. Early on, diplomates were observed directly in clinical practice as part of the certification process, but this practice was quickly discarded as impractical.[3] The first written examination (Part I) was delivered in 1937, and the first oral examination (Part II) was delivered in May 1938. Once certified, the ABS has had different requirements for how its diplomates maintain their certification over time. For nearly 40 years after the founding of the ABS, each diplomate was considered to be permanently certified unless one had an issue with their professional standing (e.g., a licensure issue), in which case the certification could be suspended. In the 1970s, the organization realized that the knowledge required to practice surgery throughout a surgeon's career could dramatically change and that surgeons should demonstrate that they were staying current in their knowledge over time. In 1976 the ABS issued its first time-limited certificate. All certificates issued from 1976 until 2017 were limited to 10 years. To maintain certification, surgeons were required to pass a secure examination at least every 10 years. This was known as *recertification* (no other requirements were in place for maintaining certification other than maintaining professional standing).

In 2000, the ABS expanded its requirements for maintaining certification to include continuing medical education (CME). Surgeons had to complete 100 credits of CME to be eligible to take the recertification examination. In 2005, the ABS further expanded the requirements to maintain certification by introducing its Maintenance of Certification (MOC) program. This was part of a broader initiative that all medical boards adhered to in recognition that board certification should be a more continuous process and that it should be broader than just a knowledge assessment.

The requirements of the MOC program retained the 10-year recertification examination while also including other requirements intended to reflect the broader nature of providing safe patient care. The program included four components: (1) Part I: Professionalism and Professional Standing; (2) Part II: Lifelong Learning and Self-Assessment; (3) Part III: Assessment of Knowledge, Judgment, and Skills; and (4) Part IV: Improvement in Medical Practice.[4]

In 2018, the ABS made significant changes to its requirements for maintaining certification. This resulted in changing the program from what was known as MOC to continuous certification.[5] The continuous certification program requires a formative assessment for learning current literature every 2 years.

Competency in Surgical Residency

As a standard-setting organization for the field of general surgery, the ABS defines the scope of general surgery and sets the standards for prerequisites of what a surgical resident needs to have completed to be eligible to obtain initial certification. Currently, these requirements include 60 months of training and 850 major operative cases across the breadth of general surgery. These requirements are enforced not only by the ABS but also by the Surgery Review Committee of the Accreditation Council for Graduate Medical Education (ACGME) as they evaluate residency programs at regular intervals.[6] It is important to recognize that the ACGME accredits residency programs, whereas the ABS certifies individuals. However, it is recognized that for individual tasks or procedures, neither time in training nor procedural volume ensures competence.[7]

The content areas of general surgery include (Essentials of General Surgery Residency Training[8]) the following:

- Alimentary tract (including bariatric surgery)
- Abdomen and its contents
- Breast, skin, and soft tissue
- Endocrine system
- Solid organ transplantation
- Pediatric surgery
- Surgical critical care
- Surgical oncology (including head and neck surgery)
- Trauma and emergency surgery
- Vascular surgery

An example of a multifaceted approach that was taken in an attempt to ensure competence of all general surgery diplomates exists in the area of flexible endoscopy. Currently, each residency graduate must complete a Fundamentals of Endoscopic Surgery (FES) curriculum during training in addition to performing at least 35 upper endoscopic procedures and 50 colonoscopy procedures. To be eligible for the ABS certification process a candidate must pass an FES written examination and a practical examination. During the certification process, each candidate has the potential to be asked questions on the qualifying (written) examination and is asked a question about endoscopic technique on the certifying (oral) examination.[9]

Additional areas of proof of competence in general surgical training include (General Surgery Training Requirements) the following:

- Advanced Cardiac Life Support (written and practical examination)[10]
- Advanced Trauma Life Support (written and practical examination)
- Fundamentals of Laparoscopic Surgery (written and practical examination)
- Six clinical performance assessments
- Six operative performance assessments

During residency, each resident's progress in training must be evaluated by the program's Clinical Competency Committee a minimum of two times each academic year. This group of educators evaluates the resident functioning in the clinical learning environment relative to the ACGME Milestones, which are based on the ACGME competencies. This evaluation process is based on data from clinical rotation evaluations and other sources such as operative assessments, clinical performance assessments, examination scores, and other performance data that are available to the program. Through this process the program can identify a resident that is not progressing toward competence at the expected rate and work with them to remediate the specific area where the underperformance was identified. At the completion of training, a global assessment of competence in all aspects of clinical practice is attested by the surgical residency program director who certifies successful completion of an accredited residency program, including assessment of technical skill.[6]

Competency Assessment in the Certification Process

The ABS is a member board of the American Board of Medical Specialties (ABMS). In its Standards for Initial Certification, the ABME requires that "Each ABMS Member Board's Standards for Initial Certification will incorporate all six ABMS/ACGME Core Competencies: Practice-Based Learning & Improvement; Patient Care & Procedural Skills; Systems-Based Practice; Medical Knowledge; Interpersonal & Communication Skills; and Professionalism."[11] After meeting the prerequisites defined by the ABS, eligible surgeons must successfully pass two examinations to become certified in general surgery.

The first examination is a written multiple-choice qualifying examination (QE). The QE is designed to assess a surgeon's knowledge level across the broad spectrum of general surgery. It is an approximately 300-item examination delivered in secure centers across the country.[12] The QE is mapped to content specifications (i.e., a test blueprint).[13] The blueprint is weighted by topic area and these weights are closely adhered to from year to year to ensure a highly standardized examination delivery for ABS candidates. All questions undergo multiple rounds of review from a panel of experts in the field. Additionally, items are evaluated based on their statistical performance and may be removed from final scoring if they do not adhere to certain criteria. Candidates who are successful on the QE are then eligible to take the oral certifying examination (CE).

The CE is designed to assess a surgeon's clinical skills in managing the diagnostic evaluation of surgical issues and providing appropriate therapy.[12] Surgeons must demonstrate the ability to manage a broad range of clinical issues. The current configuration for the general surgery CE has 13 total areas. Candidates are tested on 12 of these areas. Four areas are delivered on every examination, whereas the remaining cases are drawn from eight of nine remaining areas. The one of the nine remaining topics that does not appear on the examination alternates among the topics. Fig. 3.1 shows the examination configuration by area.

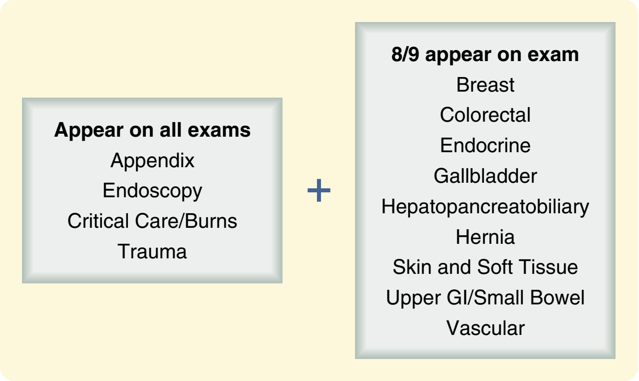

FIGURE 3.1 General Surgery Certifying Examination content areas.

The delivery of these cases is divided into three different virtual rooms with a pair of examiners in each room (for a total of six examiners). The pair of examiners in each room alternates in the delivery of the cases while both examiners score the examinee's answer on each of the four questions. The scores are totaled across all examiners and cases; candidates who are at or above the passing score are then certified.

The passing standard on both the QE and the CE are criterion-referenced cut scores. This means that performance on the examinations is judged against an absolute criterion of what is expected of a safe practicing surgeon by experts in the field. Passing standards are not normative, meaning that the pass rate is not fixed to be equal each year. It is possible to have both very high and very low fail rates, depending on the ability of the candidate cohort who takes the examination in any given year. Performance on the QE has a relatively low correlation with the CE, indicating that success on one examination does not guarantee success on the other. Candidates who perform at or above the standard become diplomates of the ABS, are "board certified," and must subsequently meet ongoing requirements to maintain their certification over the course of their career.

Board Certification and Practice Outcomes

Given the time, rigor, and effort associated with board certification, it is important to understand why surgeons engage in this process. The board certification process is voluntary, in that surgeons may practice without obtaining ABS certification (i.e., they are not prohibited from practicing by the state). However, there are many reasons a surgeon is incentivized to obtain and maintain their certification. Most hospitals, for example, use board certification as a criterion for credentialing privileges. Additionally, insurance companies and patients use board certification as an indicator of quality of care.[14]

As board certification requires such a large investment from surgeons and because the public relies on it as a quality indicator, it is important to recognize that previous research has demonstrated that board certification is associated with a variety of practice outcomes. For example, surgeons who obtained initial certification in general surgery had significantly fewer disciplinary actions than surgeons who did not obtain board certification. Additionally, failure to achieve each step in the certification process was associated with a subsequently higher rate of disciplinary actions.[15] Surgeons who failed to pass the QE had the highest rate of disciplinary actions. Surgeons who passed the QE but never passed the CE had a lower rate of disciplinary actions than those who never passed the QE, and so on. The surgeons with the lowest rate of disciplinary actions were those who passed the QE and CE on their first attempt. These findings provide not only support for board certification overall, but also for the individual examinations that define that process.

While the likelihood of receiving a disciplinary action is an important outcome, it is a broad criterion that includes variables that are not related to patient care (e.g., fraud or drug abuse). Therefore, it is also important to examine whether board certification relates to outcomes that are more directly related to patient care. One such outcome is malpractice claims, which are made as a direct result of patient care. Other research has found a relationship both with examination performance and obtaining board certification and subsequent malpractice claim rates. Surgeons who passed the QE or the CE on their first attempt had significantly lower malpractice claim rates than those that repeated those examinations. Additionally, obtaining initial certification was also associated with lower malpractice claim rates than those who were never board certified.[16]

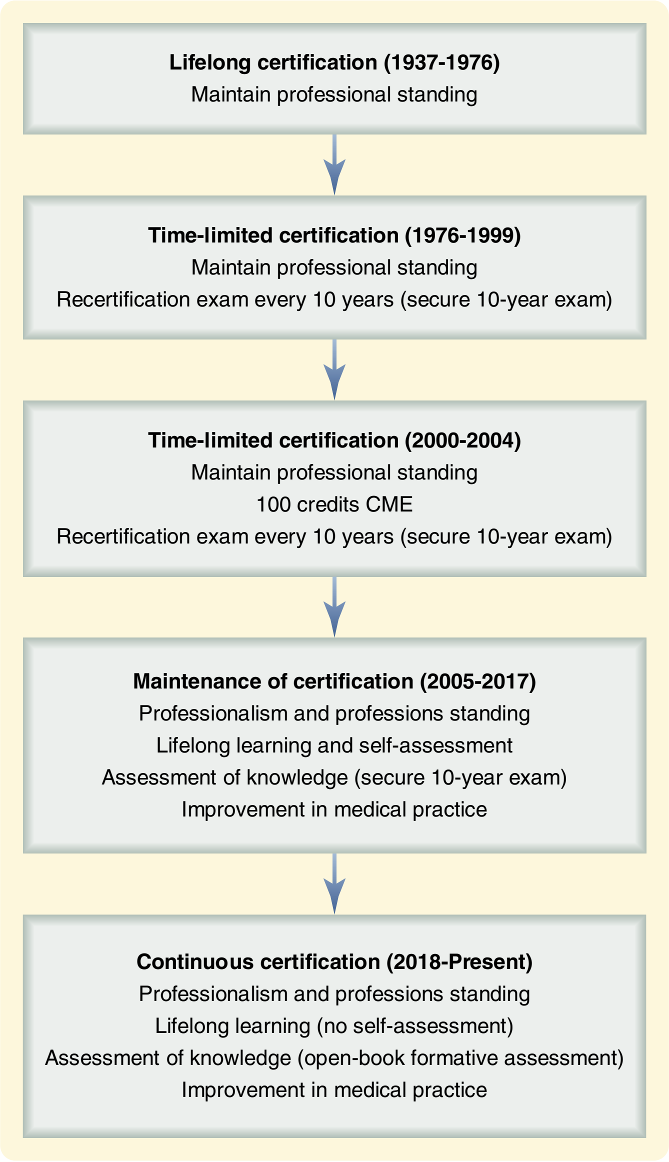
Finally, research has also investigated whether board certification is related to patient outcomes. Surgeons who are certified by the ABS have been shown to have lower patient morbidity and mortality in segmental colon resection procedures.[17] Other research has found that early-career general surgeons who obtained initial certification had reduced morbidity and mortality in partial colectomies than those who were not board certified.[18] These studies have demonstrated a direct link between board certification and quality of care.

In summary, there are many factors that either drive or are indicators of quality of care. These include but are not limited to factors like years of experience, operative volume, board certification, and participation in quality improvement.[17,19] However, very few of these factors are transparent to the public. When seeking out medical care, board certification is a transparent indicator that patients can use. Board certification is a rigorous and time-intensive investment that shows surgeons have demonstrated sufficient levels of knowledge and judgment. Each step in the process is distinct and is intended to measure different attributes to evaluate that a surgeon has met the standards set by the ABS. Once surgeons are initially certified, they must maintain a commitment to staying current in the profession by meeting ongoing requirements to remain certified throughout their career. The ABS certification and processes have been shown to be associated with important practice outcomes, which supports board certification as a tool that the public can use as one marker of competence.

Competency Assessment in the Continuous Certification Process

In 2018, the ABS made significant changes to its requirements for maintaining certification. This resulted in changing the program from what was known as MOC to what is now known as *continuous certification.* The ABS took this action based on input from both its leadership and from the diplomates. A variety of reasons were included in the rationale to make the change. There was a broad concern from the ABS leadership that testing knowledge only once a decade was too infrequent in the current era in which surgical knowledge changes rapidly. Additionally, most surgeons tended to focus their practice within a more narrow domain than the broad spectrum of general surgery.[20] This meant that surgeons who were preparing for the recertification examination had to study many topics that they perceived to be irrelevant to their practice. Preparing for the examination was also seen as burdensome because many surgeons would take multiple days off from work to attend review courses that were viewed as costly.

To address these concerns, the ABS completely redesigned the assessment component for maintaining certification. The ABS started with the principle that the assessment should be more formative in nature. This meant that the assessment should be an assessment *for* learning, rather than an assessment *of* learning. The assessments were therefore open book, with a full list of references for surgeons to review before taking the assessment. The content on the CE assessment was intentionally selected to cover recent advances in surgery. Surgeons were also granted two opportunities to answer questions (as long as they hit a minimum performance threshold on their first attempt), with the ability to look up information between their first and second attempt. To ensure that surgeons were keeping up with current advances in the field, they were now required to complete the assessment every other year, rather than once a decade. Moreover, the assessments in general



Lifelong certification (1937-1976)
Maintain professional standing
Time-limited certification (1976-1999)
Maintain professional standing
Recertification exam every 10 years (secure 10-year exam)
Time-limited certification (2000-2004)
Maintain professional standing
100 credits CME
Recertification exam every 10 years (secure 10-year exam)
Maintenance of certification (2005-2017)
Professionalism and professions standing
Lifelong learning and self-assessment
Assessment of knowledge (secure 10-year exam)
Improvement in medical practice
Continuous certification (2018-Present)
Professionalism and professions standing
Lifelong learning (no self-assessment)
Assessment of knowledge (open-book formative assessment)
Improvement in medical practice

FIGURE 3.2 Evolution of maintaining certification. *CME,* Continuing medical education.

surgery are modular so that assessments are more relevant to how surgeons practice.[5] Fig. 3.2 is an overview of the evolution of how surgeons have maintained certification over time.

Research has found a relationship between maintaining ABS certification and disciplinary actions. Surgeons who maintained their certification continuously had lower disciplinary action rates than those who allowed their certificates to lapse and those who did not maintain their certification.[21] Furthermore, surgeons who failed their first recertification examination attempt had higher disciplinary action rates than surgeons who passed their first recertification examination attempt, providing evidence that the assessment component of the program can be linked to practice outcomes.[22]

OPPORTUNITIES FOR IMPROVEMENT IN ASSESSMENT

In addition to assessing a surgeon's technical skills, competence in nontechnical skills can be assessed in a structured framework. The US-adapted Non-Technical Skills for Surgeons (NOTSS-US) has been shown to discriminate between junior and senior residents. Assessment using this framework also correlates with entrustment in performing operative procedures. However, NOTSS-US and other tools that are used to assess nontechnical skills should be considered preliminary because there is much room for improvement in the implementation of truly objective measures. To minimize subjectivity and bias, observers must be well trained and the required observation periods are typically quite long, making this labor intensive.[23]

Surgeons have long argued about the role of technical surgical skill and its impact on surgical outcomes. A study by the Michigan Bariatric Surgery Collaborative showed that much of the variability in outcomes between surgeons could be explained by differences in technical skill.[24] This study used video-based assessment (VBA) of operations performed by a voluntary cohort of surgeons that were later reviewed and scored for technical skill by another group of surgeons blinded to the identity of the operating surgeons. The surgeons that scored in the bottom quartile had an almost threefold increase in complications compared with the surgeons from the highest quartile. This was a labor-intensive project, and one of the challenges has been creating a program that could be scaled to all surgeons. The ABS conducted a pilot study of VBA from videos of laparoscopic and robotic procedures to investigate the suitability of VBA as an adjunct to certification for assessing technical skills.[25] Two hundred seventy-four surgeons participated in the pilot and based on the post pilot survey thought the feedback they obtained would help their surgical practice and would like to use it as part of their CME credits. Most thought VBA could improve surgical skills and identify and remediate underperforming surgeons. The paper concluded that "after this pilot, the ABS appreciates the value of VBA as a potential for engagement in the evaluation of actual technical performance. VBA likely plays a role in the surgical assessment and warrants inclusion in the process of surgical certification."[25]

For VBA to realize its full potential, it must lead to improvement in care, not just identification of levels of technical expertise. Multiple studies in surgery have demonstrated the feasibility of this. An example is the Video-Based Feedback for the Improvement of Surgical Technique (VISTA), which is a remote, secure, deidentified platform for operative review and feedback.[26] VBA has been used in many industries outside of medicine such as sports,[27] and coaching has been shown to enhance skill in the operating room.[28]

VBA on robotic and laparoscopic surgery is not the only modality where technical skills can be assessed. Cameras in the operating room can be used to assess open surgical procedures, percutaneous interventions, communication, and group dynamics. Additionally, sensors can be placed on the surgeon's hands or on the instruments and can give feedback about technical skill.[29]

Evidence shows a relationship between technical skills and surgical outcomes. Organizations such as the ABS, American College of Surgeons (ACS), and many other surgical organizations are working to develop practical ways to use this as part of the certification of surgeon competence matrix.

Competence and Credentialing

Certification of surgeon competence does not stop once a trainee finishes their surgical residency and any fellowship training. It is a process that continues throughout their surgical career. It happens at several levels; the first is at the level of their practice in their hospital. Those issues are regulated by the local credential and privilege systems at those hospitals. Another level is at the state level where the real issue is about obtaining and retaining a license to practice medicine and surgery. A national level includes a member board of ABMS or certifying boards of the American Osteopathic Association (AOA). An additional layer can involve payers such as the Centers for Medicare and Medicaid Services (CMS) or private insurers.

Privileging

The ACS released the "Statement on Credentialing and Privileging and Volume Performance Issues."[30] The key criteria for credentialing are listed in Table 3.1. These are mainly process measures that ensure the surgeon meets basic criteria to be granted a medical staff appointment to practice in a hospital. The more challenging issue involves the privileges to perform specific procedures. In the past, having completed surgical training in an accredited residency and appropriate board certification (or eligibility for board certification) was sufficient to grant privileges for an extensive range of practice. The ACS statement goes on to point out the following:

> *[M]ost surgical specialties encompass a range of surgical procedures. In an era characterized by the growth of surgical subspecialties and post-residency fellowship programs, institutions may seek greater clarity in the scope of surgical privileges by defining "core" and "advanced" privileges because advanced or complex procedures are often associated with a higher risk of adverse events and may require a specific skill set and supportive services, infrastructure, and resources. These definitions may vary across institutions.*[30]

Case numbers are often used as a surrogate for competence and quality. This is based on studies such as that by Birkmeyer and colleagues who studied Medicare claims data to establish an inverse relationship between surgeon case volumes and mortality in eight high-risk procedures.[30] In addition to case numbers, privileging at hospitals is governed by:

TABLE 3.1 Key Criteria and Elements of the Credentialing Process

Credentialing is the process of assessing the qualifications of physicians or other healthcare professionals. Standard objective criteria used in considering surgeons for a medical staff appointment include the following:

- Graduation from a liaison committee on medical education–accredited allopathic medical school, colleges of osteopathy, or recognized international medical schools
- Completion of an Accreditation Council for Graduate Medical Education or osteopathic-approved residency training program in a surgical discipline
- Licensure to practice medicine in the respective state
- Review of National Practitioner Data Bank reports of adverse events
- License to administer controlled substances at the national and state levels
- Certification by a member board of the American Board of Medical Specialties or an American Osteopathic Association specialty certifying board
- Verification of past performance (including review of adverse professional actions or terminations from all previous practice locations)
- Verification of any previous or ongoing liability claims and their outcomes
- Verification of medical liability insurance coverage
- A suitable practice/clinic environment to see patients
- Willingness to comply with institutional practice policies
- Verification of professional qualities, training, and experience, with confirmation from previous training directors and locations of practice
- Verification that the physician is free of any physical, mental, and cognitive impairment that would preclude the safe practice of surgery (including drug and alcohol dependence, disruptive conduct, and the adverse effects of aging)

Comprehensive review of peer recommendations may be part of the assessment before credentialing.

> *Focused Professional Practice Evaluation (FPPE), a process whereby the medical staff evaluates the privilege-specific competence of the practitioner that lacks documented evidence of competently performing the requested privilege(s) at the organization. This process may also be used when a question arises of a currently privileged practitioner's ability to provide safe, high quality patient care. A period of FPPE is required for all new privileges. This includes privileges requested by new applicants and all newly requested privileges for existing practitioners. There is no exemption based on board certification, documented experience, or reputation.*[31]

The FPPE may include proctoring or other methods to evaluate a surgeon's competence. However, those methods risk subjectivity and concerns over fairness.

State medical boards grant licenses to practice medicine and surgery in their state. They usually do not address specific procedures. The duty of the medical board, however, goes beyond the licensing and reregistration of physicians. The board is charged with the responsibility of evaluating whether a physician's professional conduct or ability to practice medicine warrants modification, suspension, or revocation of the license to practice.[32]

Payers are taking a more active role in evaluating competence of surgeons to perform procedures. Examples include CMS requirements around bariatric surgery, which in 2006 determined that covered bariatric surgery procedures are reasonable and necessary only when performed at facilities that are (1) certified by the ACS as a level 1 Bariatric Surgery Center or (2) certified by the American Society for Bariatric and Metabolic Surgery as a Bariatric Surgery Center of Excellence (BSCOE).[33] Because these designations involve specific requirements for the surgeons working in these facilities, they become a de facto assessment of surgeon competence. These rules are continually being revised, but the principle remains that payers want to make judgments about surgeon competence as part of their agreement to pay for services.

Surgical Residency Training and the Introduction of Entrustable Professional Activities

Currently the standard of competence assessment of graduates of surgery residency programs is a summative statement from the program director at the completion of training that attests to the individual's ability to practice independently. In 2016 the ABS issued a statement of intent to have surgery residency programs move to a competency-based framework. This started a journey that led to a pilot trial from 2018–2020 of five entrustable professional activities (EPAs), which are the units of competency-based education.[34–36] In this trial over 6000 observations of resident activity were documented across 28 residency programs. Some best practices to maximize faculty and resident engagement were identified during the trial. Based on this experience, the ABS committed to develop a suite of 18 EPAs to be implemented for the residency class that started in 2023 and will require the submission of EPA evaluations for all residents who sit for ABS examinations starting in 2028.[37]

The EPAs include 14 that are associated with management of diseases of specific anatomic locations and 4 that are more general:

Anatomic:

- Right Lower Quadrant (RLQ) Pain/Appendicitis
- Benign or Malignant Breast Disease

- Benign or Malignant Colon Disease
- Gallbladder Disease
- Inguinal Hernia
- Abdominal Wall Hernia
- Acute Abdomen
- Benign Anorectal Disease
- Small Bowel Obstruction
- Thyroid and Parathyroid Disease
- Dialysis Access
- Soft Tissue Infection
- Cutaneous and Subcutaneous Neoplasms
- Severe Acute or Necrotizing Pancreatitis

General:

- Provide General Surgery Consultation
- Perioperative Care of the Critically Ill Surgical Patient
- Flexible GI Endoscopy
- Evaluation/Initial Management of the Trauma Patient

It is recognized that the graduating residency class of 2028 is unlikely to be deemed "practice ready" in all 18 EPAs. For example, a survey of postgraduate year 5 (PGY5) residents in 2020 revealed that only 20% believe that they are ready to perform thyroid surgery without supervision.[38]

The existence of a competency-based evaluation process will not have wholesale impact on the number of cases or educational environment, and the data collected from the 2028 graduates are likely to largely serve as baseline data for improvement of training programs. With that said, it is expected that each candidate for the certification process will have been evaluated in the preoperative, operative, and postoperative phases of care in each EPA. The behaviors associated with different levels of performance on each EPA are clearly outlined on the ABS website.[39]

It is also recognized that the goal of a surgical residency is to produce a surgeon who is well trained in surgical principles and who is committed to the care of the surgical patient. It remains to be seen how well the EPA-based model accomplishes this. A practicing surgeon may be asked to care for many patients with conditions that do not fall specifically under the umbrella of this first iteration of EPAs. There is also potential for a resident to demonstrate competence in a given area but not demonstrate the commitment to exercise that competence in all appropriate situations. For this reason, the EPA requirements in surgical residency are not a substitute for the more global assessment processes that already exist in each residency program, although they may ultimately replace some of the preexisting assessment tools if they are seen to be redundant. It is expected that assessment via the EPA lens should significantly enhance our understanding of competency and provide more clarity of expectations for learners.

SUMMARY

The history of the ABS and its processes is deeply embedded in the pursuit of confirmation of surgical competence as the basis for certification. There is evidence to document that the past and current processes are related to surgical quality and the current path to certification requires documentation of competence in some areas and skills required for surgical practice. The rollout of EPAs as a basis for certification represents a move to increase the extent to which competence must be demonstrated before ABS certification.

Birkmeyer JD, Finks JF, O'Reilly A, et al. Surgical skill and complication rates after bariatric surgery. *N Engl J Med*. 2013;369(15):1434-1442.

A small group of bariatric surgeons was graded for skills assessment based on video review by a group of peers. The technical skill of these practicing bariatric surgeons varied widely. The greater skill was associated with fewer postoperative complications and lower rates of reoperation, readmission, and visits to the emergency department. These findings suggested that peer rating of operative skill may be an effective strategy for assessing a surgeon's proficiency.

Bonrath EM, Dedy NJ, Gordon LE, Grantcharov TP. Comprehensive surgical coaching enhances surgical skill in the operating room: a randomized controlled trial. *Ann Surg*. 2015;262(2):205-212.

A small group of cardiac surgery trainees was randomized to comprehensive surgical coaching or conventional training. Comprehensive surgical coaching comprised performance analysis, debriefing, feedback, and behavior modeling. Blinded video review was used to assess performance at the start and end of surgical rotations. Comprehensive surgical coaching enhanced surgical training and resulted in skill acquisition superior to conventional training.

Brasel KJ, Lindeman B, Jones A, et al. Implementation of entrustable professional activities in general surgery: results of a national pilot study. *Ann Surg*. 2023;278(4):578-586.

A pilot program of 28 sites was used to assess the feasibility and utility of entrustable professional activities (EPAs) in general surgery resident training. The data provided evidence that widespread implementation of EPAs across general surgery programs is possible, but variable. They provide meaningful data that graduating chief residents are entrusted by their faculty to perform without supervision for several common general surgical procedures and highlight areas to target for the successful widespread implementation of EPAs.

Kendrick DE, Chen X, Jones AT, et al. Is initial board certification associated with better early career surgical outcomes? *Ann of Surg*. 2021;274(2):220-226.

This paper looked at a Medicare database for patients undergoing a partial colectomy between 2008 and 2016 by non–subspecialty-trained surgeons in their first 5 years of practice. Patients undergoing partial colectomy by an early career general surgeon have decreased odds of severe complications and death when their surgeon is board certified.

Kopp JP, Ibáñez B, Jones AT, et al. Association between American Board of surgery initial certification and risk of receiving severe disciplinary actions against medical licenses. *JAMA Surg*. 2020;155(5):e200093.

This retrospective analysis looked at severe license action rates for surgeons who attempted ABS board certification status and examination performance. They found that obtaining board certification was associated with a lower rate of receiving severe license actions from a state medical board. Passing examinations in the certification examination process on the first attempt was also associated with lower severe license action rates. This study provides supporting evidence that board certification is one marker of surgeon quality and professionalism.

  - Use of Artificial Intelligence

INTRODUCTION

Preoperative assessment of surgical risk is a critical skill for surgeons to guide surgical decision-making, inform patient decision-making, and guide perioperative optimization. Most patients are at low risk of surgical complications, with a small portion, about 10%, being at high risk of complications.[1] Surgeons are not reliably good at identifying patients at high risk of complications after surgery.[2] The consequences of failing to identify high-risk patients are significant, leading to elevated in-hospital morbidity and mortality rates.

Accumulated experience in the fields of surgery and perioperative care coupled with advancements in science and technology have led to the refinement of surgical indications, the standardization of modern surgical techniques, and the establishment of comprehensive perioperative care protocols. Despite this, all surgery continues to carry a risk of morbidity and mortality. Although patient selection for surgical treatment is still often influenced by a surgeon's personal experience and judgment, the estimation of individual risk-to-benefit ratios for specific surgical procedures and patients can provide a more objective basis for decision-making. Here, we discuss the importance of preoperative risk assessment, examine common risk factors in the surgical population, explore current models for predicting risk and adverse events, and consider how the COVID-19 global pandemic changed the landscape of surgical risk assessment.

RISK FACTORS

Here, we review common risk factors that contribute to patient risk. These are divided into patient-related, anesthesia-related, and procedure-related risk factors.

Patient-Related Risk Factors

Age

Patient age is a commonly employed metric when evaluating patient risk for surgery; however, studies have been mixed on the direct association. Although some studies have demonstrated an association between increasing chronologic age and the risk of mortality after elective surgery,[3] others have demonstrated no difference in mortality at extremes of age when compared with matched patients not undergoing surgery.[4] Overall, agreement exists that after adjusting for comorbidities more common with age, the independent impact of age on postoperative outcomes is modest. Although older patients may benefit from increased awareness, age should not be used as the sole criterion to guide preoperative evaluation or testing or to withhold a surgical procedure.[5]

Comorbid Conditions

A patient history of comorbid conditions such as cardiovascular disease (coronary or peripheral artery disease, stroke, heart failure), chronic obstructive pulmonary disease (COPD), chronic renal failure, diabetes mellitus, obesity, hypertension, hyperlipidemia, and cancer has been shown to increase perioperative risk. A thorough history and physical examination during the preoperative assessment, as well as self-administered questionnaires and preoperative comorbidity scoring systems such as the American Society of Anesthesiologists (ASA) Physical Status Classification System (ASA class) and Charlson Comorbidity Index, can assist in objective measure of commodity burden and its implication on surgical risk. These will be discussed in the following pages.

Functional Capacity

Patient functional capacity has been shown to be a reliable predictor of surgical risk.[6,7] In general, healthy patients with at least moderate functional capacity have a low risk for major perioperative complications. Patients who report poor exercise capacity, defined as the inability to walk more than four blocks or climb more than two flights of stairs, have twice as many major postoperative complications when compared with those with good exercise capacity.[8] Functional capacity can be assessed using scoring systems such as the Duke Activity Status Index (DASI) and the Measurement of Exercise Tolerance before Surgery (METS). These will be discussed further later.

Obesity

The study of the association between obesity and postsurgical mortality has shown conflicting results in noncardiac surgery, and an "obesity paradox" has been found with high event rates with extremes of weight categories (underweight and morbidly obese) and lower mortality in overweight and obese patients as compared with normal BMI.[9-11] However, obesity has been linked to morbidities such as surgical site infections, deep vein thrombosis, and pulmonary embolism.[12,13] Specifically, when compared with normal-weight patients, overweight and obese patients in classes I, II, and III all had higher adjusted odds of developing infection, venous thromboembolism, and renal complications, but they did not exhibit elevated odds of other postoperative complications as defined by the American College of Surgeons National Surgical Quality Improvement Program (ACS NSQIP), including mortality, overall morbidity, urinary tract infection, pulmonary and cardiac issues, bleeding, stroke, unplanned readmission, or nonhome discharge (except for class III patients).[13]

Frailty

Frailty is most often defined as an aging-related syndrome of physiologic decline, characterized by marked vulnerability to adverse health outcomes. However, frailty can be applied to individuals of any age. Frail individuals often present with symptoms including weakness and fatigue, are often medically complex, and have reduced tolerance for medical and surgical interventions. Frailty is of particular importance in surgical patients because frail patients have decreased physiologic reserve and therefore may be unable to appropriately compensate after the surgical stress response. A diagnosis of frailty has been strongly associated with postoperative morbidity and mortality, increased likelihood of nonhome discharge, and increased 30-day readmission. As such, the evaluation of a patient's frailty before surgery is an important component of the risk stratification process. Frailty can be measured broadly by using either (1) the deficit accumulation model that measures deficits across various domains (medical comorbidities, function, cognition, nutrition, social, and psychological) that lead to increased vulnerability for occurrence of adverse events as proposed by Rockwood et al.[14] or (2) the phenotypic model that measures the outward manifestations of frailty such as poor endurance, low activity, slowness, and so on, as proposed by Fried et al.[15]

Anemia

Anemia, defined as a hemoglobin concentration less than 13 g/dL in males and 12 g/dL in females, is prevalent in patients with critical illness and in those presenting for surgical care. There is a strong association between anemia and perioperative morbidity and mortality. Specifically, patients with anemia have increased risk-adjusted odds of mortality, cardiac injury, respiratory dysfunction, and renal injury. Studies that stratify the degree of anemia demonstrate that the magnitude of the risk tends to progress with the severity of anemia, from mild to moderate and severe.[16]

Nutritional Status

Malnutrition significantly increases surgical risk. Specifically, malnutrition can delay the healing process after surgery, leading to slower recovery times and an increased risk of infection. Additionally, malnourished individuals may have a compromised immune system and often have electrolyte imbalances, fluid balance issues, and underlying organ dysfunction. One useful marker of preoperative nutritional status is serum albumin level. A serum albumin level >3.5 g/dL suggests adequate protein stores and confers a protective effect through several biologic mechanisms. Serum albumin level <3.5 g/dL in a noncritically ill and well-hydrated patient suggests malnutrition.[17] The patient-reported Malnutrition Screening Tool[18] assesses weight loss and appetite loss to flag high-risk patients. Preoperative assessment and optimization of nutritional status through dietary changes or supplementation in surgical patients are critical.

Glycemic Control

Perioperative dysglycemia is associated with poor surgical outcomes, including elevated risk of postoperative infection, prolonged hospital stay, and increased mortality in both cardiac and noncardiac surgical patients. Extremes of blood glucose levels, both high and low, have negative effects. In general, hyperglycemia inhibits wound healing, contributing to increased inflammation, susceptibility to infection, and, ultimately, multiorgan dysfunction.[19] Hypoglycemia, on the other hand, stimulates the release of stress hormones, which may alter cardiovascular physiology and impair cognitive function and may precede neurologic complications such as seizure and loss of consciousness. A balanced approach to glycemic management during the perioperative period, emphasizing the minimization of hypoglycemia and moderate control of hyperglycemia, is critical, and therapy should be tailored to the patient's preexisting glycemic status.[19]

Alcohol Use

Alcohol use is increasingly acknowledged as a prevalent and modifiable risk factor for surgical complications. Studies have shown that patients who consume more than four drinks daily have a two- to threefold increased risk of postoperative complications compared with those with a daily intake of fewer than two drinks, particularly cardiopulmonary, infectious, and neurologic complications.[20] Although it is clear that preoperative assessment of alcohol use is critical, straightforward questioning regarding the frequency and quantity of alcohol use during history taking lacks sensitivity and fails to identify up to 50% of surgical patients with alcohol misuse.[21] Specific tools to evaluate alcohol use and associated risks are discussed further later.

Smoking

Smoking is a well-recognized risk factor for perioperative cardiovascular, respiratory, and wound-related complications, and randomized controlled trials have shown that preoperative cessation of tobacco smoking could result in decreased rates of postoperative complications.[22] Smoking tobacco cigarettes, as well as use of nicotine replacements such as chewing gum and transdermal patches, results in systemic nicotine levels. Nicotine causes vasoconstriction through activation of nicotinic receptors in vascular smooth muscle. The resulting microvascular constriction is associated with impaired wound healing. Specifically, smoking has been associated with a significantly increased risk of postoperative wound disruption (OR 1.65, 95% CI 1.56–1.75) and surgical site infection (OR 1.31, 95% CI 1.28–1.34) compared with nonsmoking.[23] Smoking is also associated with an increased risk of postoperative pulmonary complications, and there is a dose-dependent increase in pulmonary complications based on pack-year exposure, with greater than 20 pack-years leading to a significant increase in smoking-related surgical complications.[24] Additionally, postoperative respiratory complications in smokers contribute to marginally higher inpatient costs than in never-smokers (relative cost, 1.04; 95% CI 1.00–1.07).

Medication-Related Factors

Several medications may influence the outcome of surgery, and appropriate adjustments before, during, and after surgical procedures must be made. In particular, anticoagulant and antiplatelet use receives much attention because it increases the risk of bleeding during surgery. As a generalized consideration, patients with a high risk of bleeding will benefit from anticoagulation interruption, whereas those patients with high thromboembolic risk may benefit from bridging therapy and the shortest period of anticoagulation withdrawal as possible. In these patients, increased attention should be paid to clotting parameters during hospitalization. Corticosteroid use has been shown to suppress the immune system, delay wound healing, and alter endocrine axis. Stress-dose steroid supplementation during the perioperative period may be necessary to prevent adrenal crisis in patients who chronically use steroids. Other medication classes that require close attention are diabetic medications (insulin and oral hypoglycemics, glucagon-like peptide-1 [GLP-1] receptor agonists, and sodium-glucose cotransporter-2 [SGLT2] inhibitors), antihypertensive medications such as angiotensin-converting enzyme inhibitors and β-blockers, psychiatric medications, and those with narrow therapeutic windows such as digoxin.

Anesthesia-Related Risk Factors

The type of anesthesia for a surgical procedure can have a significant effect on the overall risk profile for surgery. General anesthesia induces a state of unconsciousness and loss of sensation throughout the entire body and is typically used for more extensive surgical procedures or those that require the patient to be completely still. The main consideration with general anesthesia is the alteration of respiratory and cardiovascular physiology. General anesthesia suppresses respiratory drive and induces loss of spontaneous ventilation through neuromuscular block and depression of mediated reflexes. Even during minor surgeries in otherwise healthy individuals, general anesthetic agents can result in clinically evident changes in hemodynamics. Almost all anesthetic agents inherently possess myocardial depressant properties, though certain agents may obscure this effect through sympathetic stimulation. Additionally, the vasodilatory impact of volatile agents can lead to significant hypotension, especially when combined with their negative inotropic effects. In individuals with preexisting cardiac conditions, these cardiovascular effects of anesthesia become particularly concerning.[25] General anesthesia is also associated with postoperative cognitive changes, and some studies[26] have linked it to postoperative delirium and longer-term cognitive decline in older adults. Although alternative anesthetic protocols such as spinal anesthetic or use of regional and multimodal analgesic techniques have been advocated to reduce some of these risks, these are not uniformly applicable to patients who have comorbidities such as heart failure or need paralysis during surgery.

Procedure-Related Risk Factors

High perioperative risk is generally associated with intraperitoneal, intraabdominal, and intrathoracic procedures. In comparison, lower risk is generally associated with peripheral procedures. However, a wide variety of surgical procedures exists within each of these sites, and, as such, individualized evaluation is necessary. Additionally, procedures with increasing operative time and those associated with increased blood loss or large intraoperative fluid shifts are inherently riskier than those without. Increasing surgical complexity, as measured by the surrogate of work relative value units, is associated with increased risk of postoperative complications.[27] Relative value unit assignments are specialty specific and make it harder to compare across different specialties. Operative stress score has been proposed as a measure of surgical risk to allow cross-specialty comparison.[28]

RISK EVALUATION

We present a list of common screening tools that may be employed to assess a patient before determining treatment options, such as surgery. Findings on application of these screening tools typically prompt further focused workup, such as invasive testing or referral for evaluation by a specialist. The list presented here is not comprehensive.

General Evaluation

History and Physical Examination

A thorough history and physical examination are important in identifying and understanding possible perioperative risk factors for surgery. History should be focused on the previously mentioned patient-related risk factors, including the elucidation of existing cardiac disease, comorbid conditions, and decreased functional status. Objective examination includes the evaluation of vital signs such as blood pressure, heart rate, oxygen saturation, and BMI. Physical examination focuses on the pathology related to the chief complaint, neurologic assessment, and cardiopulmonary and vascular examination, focusing on risk factors for perioperative complications.

Preoperative Laboratory Tests

The need for specific laboratory tests before surgery is determined by the patient's medical history, the type of surgery, and the preferences and protocols of the surgical and anesthesia team and healthcare institution. The goal of preoperative testing is to identify any medical issues that might affect the safety and success of the surgical procedure and to optimize the patient's overall health and well-being. Although historically, routine laboratory testing before surgery was considered an important assessment of the fitness of patients for anesthesia and surgery, recent studies have found that the probability of identifying a clinically significant abnormality is low and rarely alters the perioperative and peri-anesthetic management of the patient.[29-31] For example, one study found that only 0.22% of laboratory testing in the elective surgery population revealed abnormalities that might influence perioperative management.[32] As such, in 2012, the ASA published guidelines recommending against routine preoperative laboratory testing for ASA class I and II patients undergoing low-risk procedures to reduce unnecessary medical expenditures, although deimplementation of routine laboratory testing has been slowly adopted.[33,34]

Cardiac-Specific Evaluation

Patients undergoing both cardiac and noncardiac surgery are at risk of postoperative cardiac adverse events. Within the scope of this chapter, we will focus on the evaluation and risk stratification of patients undergoing noncardiac surgery. It has been estimated that cardiac adverse events are responsible for roughly one-half of all mortality experienced by patients undergoing noncardiac surgery. These complications include myocardial infarction (MI), acute heart failure, hemodynamically relevant arrhythmias, and cardiac arrest or cardiovascular death.[35] Existing cardiovascular disease is a major risk factor for periprocedural cardiac adverse events, including ischemic heart disease (e.g., history of MI, angina pectoris), heart failure, cardiomyopathy, valvular heart disease, and significant arrhythmias. As such, some patients may benefit from cardiac-specific preprocedural evaluation and intervention such as medical optimization of arrhythmias, heart failure and pulmonary hypertension or coronary stenting, aortic valve replacement, or ascending thoracic aortic aneurysm repair.

Electrocardiogram

Electrocardiograms (ECGs) are commonly used as part of preoperative evaluation to assess a patient's cardiovascular health. However, the decision to perform an ECG before surgery depends on several factors, including the patient's medical history, the type of surgery being planned, and the presence of risk factors for heart disease. The specific criteria for when to order an ECG can vary among healthcare providers and institutions. In general, ECG should be considered for patients with comorbid cardiac conditions, including those with a known history of heart disease (such as coronary artery disease, heart failure, or arrhythmias), or for patients with clinical risk factors such as a history of smoking, hypertension, diabetes, obesity, and a family history of heart disease. Additionally, one should consider obtaining a preoperative ECG in patients with symptoms such as chest pain, shortness of breath, palpitations, or unexplained syncope (fainting). The 2014 American College of Cardiology and American Heart Association guidelines do not recommend routinely performing a preoperative ECG in patients who undergo low-risk surgery, which includes endoscopic and superficial procedures, cataract surgery, and breast surgery.[36]

Cardiac Stress Test

A cardiac stress test, including exercise and pharmacologic stress tests, may be warranted for certain patients before surgery, especially when there are concerns about cardiovascular health. As with many of the factors previously mentioned, the decision to perform a cardiac stress test before surgery is typically made on a case-by-case basis by the patient's surgeon, primary care provider, or cardiologist. In particular, a cardiac stress test may be recommended if the patient has a history of cardiovascular disease or risk factors for heart disease. This includes individuals with a history of angina, heart attack, coronary artery disease, heart failure, or significant arrhythmias. Similarly, older patients, typically over the age of 70, or patients with symptoms suggestive of underlying heart disease, such as chest pain, shortness of breath, poor functional status, or unexplained syncope, may be candidates for preoperative stress testing.

Echocardiogram

A preoperative echocardiogram, also known as a *preoperative cardiac ultrasound* or *echocardiography,* may be indicated for patients before surgery when there are concerns about their heart function and structure. The decision to perform a preoperative echocardiogram is typically made on a case-by-case basis by the patient's healthcare provider and surgical team. In general, resting echocardiography may be appropriate in cases where there is a notable murmur to evaluate valve function and in patients with suspected heart failure or with unexplained dyspnea to assess left ventricular function and pulmonary hypertension. Patients who have significant left ventricular systolic dysfunction, left ventricular outflow tract obstruction, or severe valvular heart disease may be more prone to the development of postoperative heart failure. Patients with pulmonary hypertension may be at increased risk of heart failure after anatomic lung resection.

Cardiopulmonary Exercise Testing

Cardiopulmonary exercise testing (CPET), also referred to as *VO_2 oxygen consumption testing,* is an important clinical tool for evaluating the objective exercise capacity and functional status of patients. Functionally, it is a noninvasive, dynamic physiologic overview of a patient's status that integrates the exercise response across the pulmonary, cardiovascular, and skeletal muscle systems and therefore accounts for aspects that are not adequately captured by assessing individual organ system functions.[37] Many different protocols are used for CPET, including both bicycle and treadmill protocols. During the exercise, which is symptom limited, a patient's respiratory oxygen uptake (VO_2), carbon dioxide production (VCO_2), and ventilation are measured. CPET has the ability to differentiate between a typical and an anomalous exercise response, which enables referral for further procedures with enhanced diagnostic precision, such as further cardiac or pulmonary evaluation. As such, CPET is recommended as one of the initial assessments for evaluating exercise intolerance.

Metabolic Equivalent of Task

The preoperative evaluation of the metabolic equivalent of task (MET) is a straightforward clinical assessment of an individual's functional capacity or exercise tolerance. One MET is defined as resting metabolic rate in a sitting position, representing the amount of oxygen consumed at rest (approximately 3.5 mL O_2/kg/min or 1.2 kcal/min for a 70-kg person).[38] The maximum amount of metabolic work that an individual can perform corresponds to overall cardiovascular fitness. A meta-analysis demonstrated that for healthy individuals, the ability to generate each additional MET correlated with a 13% decrease in the likelihood of all-cause mortality and a 15% decrease in the risk of long-term coronary heart/cardiovascular disease events.[39] In the clinical setting, a patient's maximum METs can be simply assessed by asking them for a description of their physical activities. For example, patients who can perform light housework are able to generate 2 to 3 METs, and those who can climb stairs generate 4 METs (Fig. 4.1). Traditionally, those patients who are unable to perform >4 METs of activity are considered to have poor functional status, and it has been well documented that patients with low METs are at increased risk for perioperative morbidity and

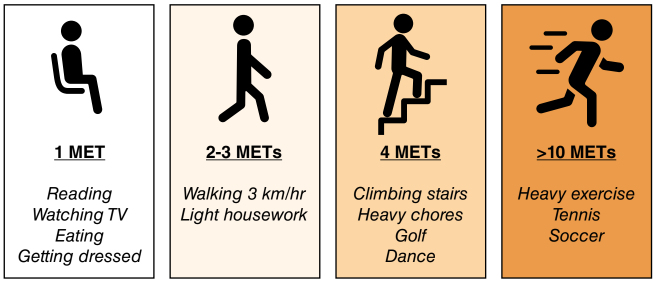

FIGURE 4.1 Metabolic equivalents of task *(METs).*

mortality.[40] Patients with low METs upon testing may benefit from further evaluation through specialty consultation, for example, with cardiologists or pulmonologists.

Cardiac Laboratory Tests

As with generalized laboratory tests, obtaining preoperative cardiac laboratory testing should be based on positive clinical history or suspicion by the surgical and anesthesia team. Routine use of biomarkers such as B-type natriuretic peptide (BNP) or troponin is not recommended, as their use for preoperative risk stratification has not yet been associated with improved clinical outcomes. However, BNP in particular may be helpful for guiding preoperative workup in patients for whom the decision to undergo further preoperative cardiac testing is unclear. In this setting, a low BNP/aminoterminal pro BNP (N-terminal pro-BNP [NT-proBNP]) value may suggest that the patient's risk is relatively low. A higher level would warrant additional workup, discussion, and shared decision-making between the patient, surgeon, and consultant. A meta-analysis of 18 studies examining the prognostic value of BNP for noncardiac surgery demonstrated that BNP $\geq$92 ng/L was associated with increased risk of cardiac death or nonfatal MI.[41] Regarding troponin, the American Heart Association guidelines do recommend obtaining a preoperative troponin level, and most clinicians do not routinely order them. However, the 2022 European Society of Cardiology guidelines recommend obtaining preoperative troponins in patients $>$65 years old or those with cardiac risk factors undergoing intermediate- to high-risk surgery.[42]

Respiratory-Specific Evaluation

Postoperative pulmonary complications significantly contribute to both the mortality and complication rates associated with surgical procedures. These complications include atelectasis, pneumonia, acute respiratory distress syndrome, and respiratory failure. Prior reports have indicated that 5% to 10% of all surgical patients and 9% to 40% of those undergoing abdominal surgery encounter postoperative pulmonary complications.[43] However, the definition of what constitutes such complications has varied considerably in previous studies. Patients who have preexisting pulmonary conditions, such as sleep apnea, are at increased risk for respiratory complications after surgery.[44] As such, patients with existing disease may benefit from undergoing respiratory-specific evaluation before surgery.

Hypoxia and Hypercarbia

Assessment of oxygen saturation (SpO_2) through oximetry is important, particularly before high-risk surgery. In particular the Assess Respiratory Risk in Surgical Patients in Catalonia (ARISCAT) risk index and the Gupta Calculator for Postoperative Respiratory Failure incorporate this measurement into risk stratification and are discussed further later. Although arterial blood gas (ABG) analysis is not commonly necessary in routine preoperative assessments, there are instances where it may be considered based on clinical indicators. In general, patients with hypercapnia are often identified based on established clinical risk factors, such as severe COPD or neuromuscular disease, rather than by routine ABG before surgery. It has been suggested that patients with a $PaCO_2$ $>$45 mm Hg have increased postoperative pulmonary complications, although this is likely related to their severe COPD.[45]

Pulmonary Function Testing

Pulmonary function tests (PFTs) are generally not considered necessary for the majority of patients undergoing extrathoracic surgery because studies have found that PFTs do not consistently predict pulmonary complications in patients undergoing abdominal surgery.[46] In most patients, PFTs simply confirm the clinical impression garnered from history taking and physical examination without significantly enhancing risk estimation. PFTs should be considered for patients with COPD or asthma if clinical evaluation cannot determine the patient's optimal baseline or disease severity. PFTs may also be considered in patients for whom history taking reveals severe unexplained dyspnea or exercise intolerance. In such cases, PFT results may help diagnose issues such as cardiac disease or deconditioning and affect preoperative management. Previous reviews have suggested forced expiratory volume in 1 second (FEV_1) $<$70% predicted, forced vital capacity (FVC) $<$70% predicted, and FEV_1/FVC ratio $<$0.65 are all correlated with increased risk.[46]

Chest Radiograph

Generally, routine chest radiographs are not recommended as part of the workup for existing pulmonary disease unless there are indications of undiagnosed or unstable cardiopulmonary conditions, such as new or worsening exertional dyspnea, wheezing, angina, orthopnea, lower extremity edema, hypoxemia, rales/rhonchi, or the presence of a heart murmur.

Geriatric-Specific Evaluation

Older adults ($\geq$65 years of age) account for a disproportionately large number of all surgical procedures performed in the United States. Although increasing age is a risk factor for perioperative mortality, comorbidity burden and the invasiveness of the planned surgical procedure are the most important predictors. However, geriatric conditions such as functional or cognitive impairment are frequently unrecognized or inadequately addressed in the perioperative period. Identifying geriatric conditions by performing a geriatric assessment can help clinicians manage these conditions and prevent or delay their complications.

Comprehensive Geriatric Assessment

A comprehensive geriatric assessment (CGA) is a diagnostic process often performed by an intensive multidisciplinary team aimed at identifying medical, psychosocial, and functional limitations of older patients to develop an actionable, coordinated plan to maximize overall health with aging. The core components of the CGA are cognition, mood, functional capacity, fall risk, polypharmacy, social support, financial concerns, goals of care, and advanced care preferences. Although the principles and processes of the CGA are generally used to evaluate community-dwelling older patients with functional disability, frailty, increased fall risk, cognitive decline, depression, or those at high risk for high healthcare utilization, they are being increasingly applied in the evaluation of fitness for surgery.[47]

Mini-Cog

The Mini-Cog is a brief cognitive screening tool that was developed as a quick and effective way to identify individuals who may have cognitive impairment. The test consists of two parts: the three-item recall and the clock drawing task. The individual is first presented with three unrelated words and asked to remember them; then they are asked to draw the face of a clock, including all the numbers and setting the hands to a specific time. The scoring system is simple. One point is given for each word correctly recalled from the three-item recall task, and one point is given for a correct clock drawing. A total score of three indicates normal cognitive function, whereas a lower score may suggest cognitive impairment. It is important to note that the Mini-Cog is a screening tool and not a diagnostic tool. If the results of the Mini-Cog suggest cognitive impairment, further evaluation by a healthcare professional is typically recommended to determine the cause and extent of cognitive decline.

Montreal Cognitive Assessment

The Montreal Cognitive Assessment (MoCA) is a more extensive, widely used screening tool designed to assess several domains of cognitive function, including memory, attention, language, and visuospatial skills. It was developed to detect mild cognitive impairment and early stages of dementia, particularly Alzheimer disease. The MoCA consists of several tasks and questions covering different cognitive domains. To test visuospatial and executive functioning, tasks involve drawing a specific shape, connecting numbered dots, or copying a cube. Naming is tested by showing various animals and asking the patient to name them within a specific time limit. Memory is tested by asking patients to recall a list of words. The domain of attention and concentration is assessed by having patients perform tasks such as serial subtraction. Language is assessed using sentence repetition and verbal fluency. For abstraction, patients are asked to interpret common proverbs. The maximum score on the MoCA is 30 points, with a score of 26 or above generally considered normal. However, interpretation may vary based on factors such as age and education level. Lower scores may suggest cognitive impairment, and individuals with lower scores are often recommended for further evaluation. It is important to note that although the MoCA is a valuable tool for detecting cognitive impairment, a comprehensive assessment by a healthcare professional is necessary for a definitive diagnosis and appropriate management.

Psychosocial Evaluation

Psychosocial factors such as behavioral traits, mental illness, resilience, and resourcefulness, as well as available social support, all have important implications on a patient's ability to cope with the stress of surgery, to comply with appropriate postoperative follow-up, and to effectively self-manage their postoperative care. Ultimately, mental illness and lack of ability to cope with stressors may increase the risk and magnitude of postoperative complications. Anxiety has been shown to predict short-term operative morbidity, length of stay, and patient-reported ratings of recovery, whereas depression has been correlated with patient reports of long-term pain. Attitudinal factors, particularly self-efficacy and patient-perceived control, were associated with earlier functional recovery.[48] Although broad consensus exists that psychosocial risk factors are relevant to operative and postoperative courses, psychosocial risk assessment is rarely objective and often is conventionally performed with a surgeon's gestalt. Often-recommended distress screening tools include the Generalized Anxiety Disorder-7 (GAD-7) scale and the Patient Health Questionnaire-9 (PHQ-9). However, these do not reflect the complex psychosocial situation of many adults.

RISK ASSESSMENT TOOLS

Global Risk Assessment Tools

American Society of Anesthesiologists Physical Status Classification System

The ASA class system is a frequently used system that provides a framework for simple categorization of a patient's physiologic status. It was first published in 1941.[37] Importantly, the ASA class system was neither developed nor intended to be used to predict risk with surgery or anesthesia, but rather as a way to summarize preoperative comorbidity status and extent of a patient's systemic disease. In the most familiar form, it uses five tiers of classification, ranging from ASA class I, assigned to a normal healthy patient, to ASA class V, summarizing a moribund patient who is not expected to survive without the operation. Notably, the system now includes class VI, which corresponds to a patient declared brain dead whose organs are being removed for donor purposes (Table 4.1). Unsurprisingly, studies have linked increasing ASA class with increasing rates of morbidity and mortality.[49] Overall, a major strength of the ASA class system is its simplicity, as it requires few variables and no complex computations. Because of this, it is frequently used internationally and across multiple medical specialties and is a ubiquitous component of clinical investigations.[50] However, the ASA has been criticized for its subjective nature, and several studies have demonstrated the tremendous variability and inconsistency in the classification of any one patient.[51] Nonetheless, ASA classification may assist in making simple informed decisions and has been correlated with some meaningful outcomes.[52]

Charlson Comorbidity Index

As an improvement on the subjective nature of the ASA class system, the Charlson Comorbidity Index is a weighted index initially developed to predict risk of death within 1 year of hospitalization

TABLE 4.1 **ASA Physical Status Classification System**

CLASSIFICATION	DESCRIPTION	EXAMPLE
ASA I	A normal healthy patient	Healthy, nonsmoking patient
ASA II	A patient with mild systemic disease	Current smoker; pregnant; mild obesity; well-controlled diabetes or hypertension
ASA III	A patient with severe systemic disease that limits activity but is not incapacitating	Poorly controlled diabetes, hypertension or COPD; morbid obesity; alcohol dependence; end-stage renal disease undergoing regular dialysis
ASA IV	A patient with an incapacitating systemic disease that is a constant threat to life	Recent (<3 month) myocardial infarction or cerebrovascular accident; severe valvular dysfunction; shock; sepsis; acute renal failure
ASA V	A moribund patient not expected to survive 24 hours without operating	Ruptured aneurysm; massive trauma
ASA VI	A patient declared brain dead whose organs are being removed for donation purposes	Organ donor patient
E	Suffix for patients undergoing emergency procedures	

ASA, American Society of Anesthesiologists; *COPD,* chronic obstructive pulmonary disease.

TABLE 4.2 **Charlson Comorbidity Index**

SCORE	CONDITION
1	Myocardial infarction
1	Congestive heart failure
1	Peripheral vascular disease
1	Cerebrovascular disease
1	Dementia
1	Chronic pulmonary disease
1	Connective tissue disease
1	Peptic ulcer disease
1	Mild liver disease (without portal hypertension)
1	Diabetes (without end-organ dysfunction)
2	Hemiplegia
2	Moderate to severe renal disease
2	Diabetes (with end-organ dysfunction)
2	Tumor (without metastases)
2	Leukemia
2	Lymphoma
3	Moderate to severe liver disease
6	Metastatic solid tumor
6	Acquired immunodeficiency syndrome
37	*Total score*

for patients with specific comorbid conditions. Each condition is assigned a weight from 1 to 6, based on the estimated 1-year mortality hazard ratio from a Cox proportional hazards model (Table 4.2). This is a useful scoring system, including in the clinical setting and for risk adjustment for research purposes. Similar to the ASA class, it is easily administered; however, unlike the ASA class, it should yield near-identical results by scorer because of objective scoring.[53] It is a validated, simple, and readily applicable method of estimating the risk of death from comorbid disease and has been widely used as a predictor of long-term prognosis and survival. Although the Charlson Comorbidity Index was originally proposed in 1987 with 19 categories,[54] it was modified in 1992 by Deyo et al. to 17 categories.[55] Following these modifications, each comorbidity category has an associated weight (from 1 to 6), based on the adjusted risk of mortality or resource use, and the sum of all the weights results in a single comorbidity score for a patient. A score of zero indicates that no comorbidities were found. The higher the score, the more likely the predicted outcome will result in mortality or higher resource use.

American College of Surgeons Surgical Risk Calculator

The ACS NSQIP collects high-quality, standardized clinical data on preoperative risk factors and postoperative complications from more than 500 hospitals in the United States.[56] Published in 2013, these data were used to develop an online surgical risk calculator, which has found widespread application in the clinical setting in over 1500 types of surgeries. Using data from several million surgical patients, the calculator accounts for various patient-specific factors, including age, sex, medical history, and the type of surgical procedure, to provide an individualized risk assessment for a given patient and estimates the likelihood of various common postoperative complications, such as surgical site infections, pneumonia, and other adverse events. The model requires entry of 21 patient-related variables and provides the option for the user to increase the patient's complexity. The calculator has shown excellent performance for mortality (c-statistic = 0.944, Brier score = 0.011 [where scores approaching 0 are better]) and morbidity (c-statistic = 0.816, Brier score = 0.069). Additionally, when tested against surgeons, it demonstrated considerable agreement on the case scenario scoring. The ACS NSQIP Surgical Risk Calculator is a decision support tool based on reliable multi-institutional clinical data, which can be used to estimate the risks of common operations, allowing clinicians and patients to make decisions using empirically derived, patient-specific postoperative risks.[56] A recent update to the algorithms include use of artificial intelligence methods applied to the ACS NSQIP dataset.[57] However, the ACS NSQIP Surgical Risk Calculator algorithms have not been published and are not available for research application or validation outside of the ACS.

Surgical Risk Preoperative Assessment System

In an effort to improve on the clinical utility of prior calculators, the Surgical Risk Preoperative Assessment System (SURPAS) was developed as a parsimonious, patient-centered, patient-facing, clinical decision support tool.[58-60] The authors of SURPAS reasoned that a surgical risk assessment tool should be quick and easy to use, integrated into the electronic health record, provide reliable and meaningful risk estimates broadly encompassing many different types of surgery and surgical complications, based on readily available preoperative data, incorporated into the preoperative note, available to the public/transparent, and updated periodically.[61] SURPAS is an individualized, preoperative risk assessment system that uses the input of nine variables present at the time of preoperative decision-making (Current Procedural Terminology [CPT]–associated risk,[62] work relative value unit,[27] operation, patient age, functional status, ASA class, inpatient/outpatient operation, emergency operation, surgeon specialty) to accurately predict the risk of 16 postoperative complications (mortality, overall morbidity, unplanned readmission, infection, bleeding requiring transfusion, pulmonary morbidity, urinary tract infection, venous thromboembolic, cardiac morbidity, renal morbidity, stroke, nonhome discharge, need for intensive care unit admission, unplanned reoperation, outpatient to inpatient conversion, and length of stay in days) occurring within 30 days after surgery.[63-68] Of note, in a recent study of surgical patients treated at a multisite hospital system, high social vulnerability index was associated with multiple adverse outcomes even after risk adjustment for preoperative clinical factors.[69] However, the SURPAS prediction model was not significantly improved by addition of the social vulnerability index, a surrogate for social determinants of health. Thus, the SURPAS tool functions well without including an additional measure of social vulnerability.[70]

SURPAS applies to patients undergoing surgery in 10 surgical specialties: general, cardiac, gynecologic, orthopedic, otolaryngologic, plastic/reconstructive, thoracic, urology, vascular, and neurosurgery. The authors of SURPAS determined that many surgical outcomes reported by the ACS NSQIP could be cohorted based on factor analysis and that laboratory values did not substantially change risk predictions and thus could be eliminated from the possible independent risk predictors.[59,60] It was developed from the ACS NSQIP dataset and has been internally and externally validated in broad and specific patient populations.[71-73] SURPAS has been shown to be more reliable and accurate in predicting patient risk than surgeons.[2] When compared with the ACS NSQIP Surgical Risk Calculator, SURPAS's risk predictions have been shown to perform similarly for mortality more accurately than for overall morbidity, particularly for high-risk patients.[74,75] In addition to SURPAS being applicable to high-risk procedures,

TABLE 4.3 Surgical Risk Preoperative Assessment System Model Information Based on ACS NSQIP PUF 2011–20

MODEL	SAMPLE SIZE	EVENT RATE/ MEAN FOR EACH OUTCOME	C-INDEX	BRIER SCORE	YEARS TO DETERMINE FREQUENCY FOR CPT EVENT RATE/MEAN[a]	EXCLUSIONS FROM RISK PROFILES IN SURPAS
Mortality	8,225,826	1.0% (81,324)	0.925	0.0087	2005–20	None
Overall morbidity	8,225,826	11.9% (975,742)	0.820	0.0843	2005–20	None
Respiratory	8,225,826	2.3% (189,647)	0.891	0.0225	2005–20	None
Infection	8,225,826	4.6% (377,365)	0.798	0.0404	2005–20	None
Urinary tract infection	8,225,826	1.3% (107,997)	0.765	0.0130	2005–20	None
Venous thromboembolism	8,225,826	0.8% (67,019)	0.773	0.0080	2005–20	None
Cardiac	8,225,826	0.6% (52,190)	0.869	0.0062	2005–20	None
Renal	8,225,826	0.5% (41,841)	0.861	0.0050	2005–20	None
Stroke	8,225,826	0.2% (16,082)	0.839	0.0019	2005–20	None
Bleeding requiring transfusion	8,225,826	5.2% (427,153)	0.883	0.0409	2010–20	None
Nonhome discharge	8,136,964	8.2% (668,059)	0.913	0.0517	2011–20	None
Unplanned readmission	7,788,372	4.0% (307,930)	0.725	0.0370	2012–20	None
Unplanned reoperation	7,788,372	2.8% (216,026)	0.749	0.0262	2012–20	None
Conversion from outpatient to inpatient hospitalization[b]	3,223,081	3.9% (126,361)	0.818	0.0335	2005–20	Does not apply to risk profiles for inpatients, having an emergency case, or patients with ASA class of IV or V
Length of stay[c]	4,664,511	3.9 days (4.0 SD)	0.5603	NA	2005–20	Does not apply to risk profiles for outpatients
Need for intensive care unit admission[d]	34,568	7.4% (2,545)	0.914	0.0449	NA	None

[a] Date ranges differ because of definition changes of outcome or inclusion of outcome to the PUF at later dates. Missing data and exclusions also contribute to different sample sizes and frequency rates.

[b] An outpatient's risk of being converted to an inpatient status during the surgical procedure. Exclusions from the model included emergency status, ventilator dependent, inpatient, sepsis or septic shock, and ASA class IV and V.

[c] Length of stay was days from index operation to discharge. Exclusions from the model included outpatient and patients that died within 30 days or discharge destination was expired.

[d] ICU stay was developed on local NSQIP data and does not necessarily represent a national risk estimate. Because there is no national event rate, there is no CPT event rate for this outcome.

ACS NSQIP, American College of Surgeons National Surgical Quality Improvement Program; *CPT,* Current Procedural Terminology; *NA,* not applicable; *PUF,* Participant Use Data File.

models have been developed to account for low-volume procedures occurring fewer than 100 times in the ACS NSQIP dataset. SURPAS has shown excellent performance for mortality (c-statistic = 0.938) and overall morbidity (c-statistic = 0.810). The multivariable logistic regression models and b-coefficients are updated yearly from the prior decade's ACS NSQIP dataset and have been published and are online, providing transparency and facilitating implementation (Table 4.3).[76] SURPAS has been implemented in the local electronic health record of a multihospital health system, where it autopopulates some of the predictive variables, and has been made freely available online.[76,77] The clinical implementation of SURPAS includes provision of a printable handout for the provider to review and share with patients and their families. This was developed through patient focus groups to show patients their predicted risk of outcomes compared with outcomes from the same operation observed in the ACS NSQIP data. Patients have reported that seeing their risk through the SURPAS application has decreased their preoperative anxiety compared with the routine preoperative risk and consent discussion, which actually increased anxiety.[77-79]

9-Point Surgical Mortality Probability Model

To improve on the nonparsimonious ACS NSQIP Surgical Risk Calculator, the 9-Point Surgical Mortality Probability Model (S-MPM) was developed.[80] It contains, in a simplified form, the two most important risk components—patient risk (via the ASA class) and operational risk (emergency status and surgery risk class)—and was developed to be used at "point of care." To calculate the index, patients who are ASA class I, II, III, IV, or V are assigned 0, 2, 4, 5, or 6 points, respectively; intermediate- or high-risk procedures are assigned 1 or 2 points, respectively; and emergency procedures are assigned 1 point (see Table 4.2). The model has shown that patients with risk scores less than 5 have a predicted risk of mortality less than 0.50%, whereas patients with a risk score of 5 to 6 had a risk of mortality between 1.5% and 4.0%, and patients with a risk score greater than 6 have a risk of mortality more than 10%. This tool has been externally validated.[81]

Other surgical risk calculators have been developed and published. Some of these have been developed to address specific patient populations based on disease state, patient age, and occurrence of trauma.

TABLE 4.4 Revised Cardiac Risk Index

POINTS	CLINICAL VARIABLE
1	High-risk surgery
1	History of ischemic heart disease
1	History of congestive heart failure
1	History of cerebrovascular disease
1	Insulin treatment for diabetes
1	Preoperative serum creatinine >2.0 mg/dL
TOTAL POINTS	**RISK CLASSIFICATION**
0	(I) Very low risk: 0.4% risk of complications
1	(II) Low risk: 0.9% risk of complications
2	(III) Moderate risk: 7.0% risk of complications
3+	(IV) High risk: 11.0% risk of complications

Cardiac Risk Assessment Tools

Revised Cardiac Risk Index

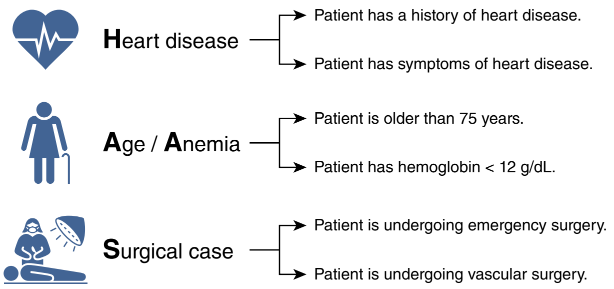
The Revised Cardiac Risk Index (RCRI) was developed to evaluate the risk of cardiac complications in patients undergoing noncardiac surgery. The RCRI takes into account six independent clinical risk factors associated with an increased risk of cardiac events in the perioperative period, including type of surgery (intraperitoneal, intrathoracic, or suprainguinal vascular), history of ischemic heart disease, history of congestive cardiac failure, history of cerebrovascular disease, use of insulin therapy for diabetes, and preoperative serum creatinine >2 mg/dL.[82] It assigns points for each of the six risk factors, with higher scores indicating a greater risk of cardiac events (Table 4.4), and has been validated in multiple studies.[83] The European Society of Cardiology, the European Society of Anesthesiology, the American College of Cardiology, and the American Heart Association have all included use of the RCRI in their guidelines for preoperative cardiac risk assessment and management for noncardiac surgeries.

Gupta Perioperative Myocardial Infarction or Cardiac Arrest Calculator

The Gupta Perioperative Myocardial Infarct or Cardiac Arrest (MICA) calculator, which is derived from the ACS NSQIP data, assesses the perioperative risk of intraoperative or postoperative MI and cardiac arrest after noncardiac surgeries. Similar to the RCRI, this calculator is based on the type of surgery, functional status, serum creatinine, ASA class, and increased age as variables.[84] The MICA calculator has been validated in several populations.[84-86]

American University of Beirut Medical Center

The American University of Beirut Medical Center (AUB)-HAS2 cardiovascular risk index is a simple and powerful discriminatory model used to predict cardiovascular events after noncardiac surgery. It was derived from a small prospective cohort of patients undergoing noncardiac surgery at the American University of Beirut but was validated using the ACS NSQIP database.[87] Similar to other calculators, the AUB-HAS2 index is based on six easily acquired predictor variables: history of heart disease, symptoms of heart disease (angina or dyspnea), age ≥75 years, anemia with hemoglobin <12 mg/dL, and undergoing either vascular or emergency surgery (Fig. 4.2).



Heart disease
Patient has a history of heart disease.
Patient has symptoms of heart disease.
Age / Anemia
Patient is older than 75 years.
Patient has hemoglobin < 12 g/dL.
Surgical case
Patient is undergoing emergency surgery.
Patient is undergoing vascular surgery.

FIGURE 4.2 American University of Beirut Medical Center (AUB)-HAS2.

Respiratory Risk Assessment Tools

Assess Respiratory Risk in Surgical Patients in Catalonia

The ARISCAT is a scoring system used to evaluate the risk of postoperative pulmonary complications in patients undergoing surgery, including pneumonia, atelectasis, or respiratory failure. The ARISCAT score takes into account various patient-related and surgical factors to estimate the risk of these complications, including age, preoperative oxygen saturation, type of surgery (e.g., abdominal, thoracic, head and neck), surgical approach (open vs. minimally invasive), duration of surgery, serum creatinine levels, and emergency surgery status. Patients receive varying points for each of the predictors (Table 4.5), which categorizes them into a risk class—low, intermediate, or high—corresponding to a pulmonary complication rate of 1.6%, 13.3%, and 42.1%, respectively.[88] The ARISCAT has been externally validated.[89]

TABLE 4.5 Assess Respiratory Risk in Surgical Patients in Catalonia (ARISCAT)

RISK FACTOR	SCORE
Age (years)	
≤50	0
51–80	3
>80	16
Preoperative SpO_2	
≥96%	0
91%–95%	8
≤90%	24

TABLE 4.6 **Arozullah Respiratory Failure Index**

RISK FACTOR	POINTS
Type of Surgery	
Abdominal aortic aneurysm	27
Thoracic	21
Neurosurgery	14
Upper abdominal	14
Peripheral vascular	14
Neck	11
Emergency classification	11
Albumin <3.0 g/dL	9
BUN >30 mg/dL	8
Partially or fully dependent	7
History of COPD	6
Age (years)	
≥70	6
60–69	4
RISK CLASS	**TOTAL POINTS**
Class 1	≤50
0.5% risk of respiratory failure	
Class 2	11–19
1.8% risk of respiratory failure	
Class 3	20–27
4.2% risk of respiratory failure	
Class 4	28–40
10.1% risk of respiratory failure	
Class 5	>40
26.6% risk of respiratory failure	

BUN, Blood urea nitrogen; *COPD,* chronic obstructive pulmonary disease.

Arozullah Respiratory Failure Index

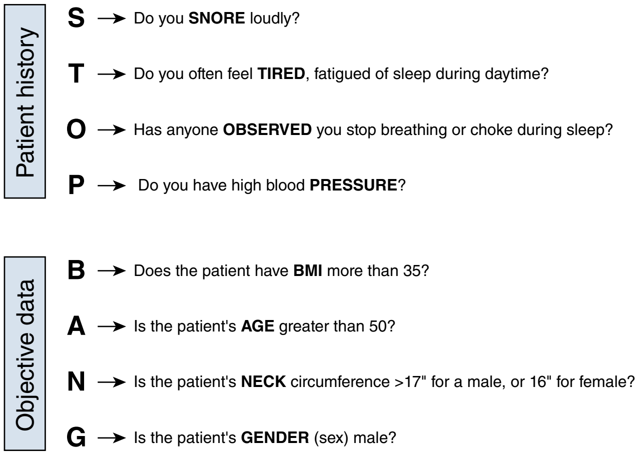
The Arozullah Respiratory Failure Index uses a simplified logistic regression model incorporating type of surgery (abdominal aortic aneurysm repair, thoracic surgery, neurosurgery, upper abdominal surgery, peripheral vascular surgery, neck surgery, or emergency surgery), preoperative albumin level below 30 g/L, preoperative blood urea nitrogen level exceeding 30 mg/dL, patient functional status, the presence of COPD, and age. For each of the factors, patients get various points (Table 4.6) and, similarly to other risk indexes, are stratified into risk classes.

STOP-BANG Obstructive Sleep Apnea Assessment

The STOP-BANG index is a screening tool used to assess the risk of obstructive sleep apnea in individuals.[44] The acronym STOP-BANG represents eight yes/no questions related to sleep and breathing patterns. Each letter in the acronym corresponds to a specific question (Fig. 4.3). For all eight of the questions, each "yes" is assigned 1 point, and the total score ranges from 0 to 8. A higher score indicates a higher likelihood of having obstructive sleep apnea.

Gupta Calculator for Postoperative Respiratory Failure

Postoperative respiratory failure is defined as the inability to successfully transition from mechanical ventilation within 48 hours of surgery or unplanned intubation/reintubation postoperatively and is linked to significant increases in length of hospital stay, morbidity, and mortality.[90] The impact of postoperative respiratory failure on patient outcomes underscores its importance as a critical aspect of postoperative care, necessitating attention and proactive management. Preoperative factors linked to an increased risk of postoperative respiratory failure include the nature of the surgery, emergency status, dependent functional status, sepsis, and a higher ASA class. The Gupta score is a validated online risk calculator developed to estimate the likelihood of postoperative respiratory failure using these variables.[91]



S → Do you **SNORE** loudly?

T → Do you often feel **TIRED**, fatigued of sleep during daytime?

O → Has anyone **OBSERVED** you stop breathing or choke during sleep?

P → Do you have high blood **PRESSURE**?

B → Does the patient have **BMI** more than 35?

A → Is the patient's **AGE** greater than 50?

N → Is the patient's **NECK** circumference >17" for a male, or 16" for female?

G → Is the patient's **GENDER** (sex) male?

FIGURE 4.3 STOP-BANG questionnaire.

Additional tools for respiratory complication evaluation exist. These include the Respiratory Failure Risk Index (VASQIP),[90] the NSQIP pneumonia risk tool and respiratory failure risk tool, the LAS VEGAS tool,[92] the Surgical Lung Injury Prediction mode, and the Score for Prediction of Postoperative Respiratory Complications.[93]

Functional Status Screening Tools

Duke Activity Status Index

The DASI is a questionnaire used to gauge a patient's functional capacity. Its primary application has been in the evaluation of patients with cardiovascular conditions, including coronary artery disease, heart failure, MI, and infarction. In clinical settings, DASI proves valuable for assessing the impact of medical interventions and cardiac rehabilitation, as well as aiding in clinical decision-making regarding the risk or benefit of surgery.[7] The DASI is a 12-item scale that is well correlated with peak oxygen uptake (Spearman correlation coefficient 0.80). Positive responses to the weighted questions are summed to get a total score, which ranges from 0 to 58.2. Higher scores indicate higher functional capacity.

Frailty Screening Tools

Risk Analysis Index

The Risk Analysis Index (RAI) was developed to function as an effective frailty screening tool before elective surgery. The RAI, which is an adaption of the Minimum Data Set Mortality Risk-Index Revised,[94] assesses 11 preoperative variables and calculates the risk index based on patient-provided answers to 14 questions assessing 11 variables.[95] The variables encompass five domains of frailty (social, function, cognitive, physical, and nutritional) and include demographic factors (age, sex), comorbidities (presence of disseminated cancer, unintentional weight loss, renal failure, congestive heart failure, poor appetite, and dyspnea at rest), cognitive decline, facility residence, and level of independence in four activities of daily living. It has been validated in large surgical registries retrospectively (RAI-A) to allow big data analyses and in prospective cohorts (RAI-C) for real-time implementation

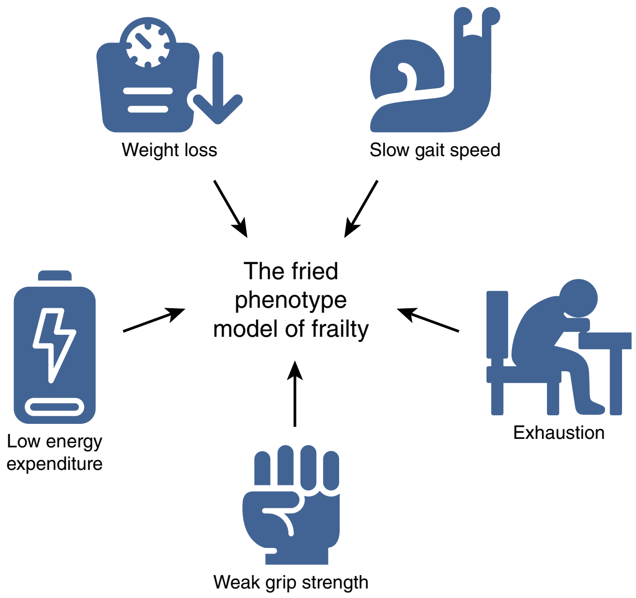


FIGURE 4.4 Frailty phenotype.

as a frailty screening tool.[96] It has been adopted nationally by the Veterans Health Administration (VHA) for perioperative risk assessment,[97] and an intervention model called the Surgical Pause and a cluster randomized trial (PAUSE trial) testing a multidisciplinary intervention are currently underway to test effectiveness and implementation of the model.

Frailty Phenotype

Although the concept of frailty is well established in literature, its practical translation and definition remain controversial. The frailty phenotype is based on a predefined set of five criteria exploring the presence or absence of signs or symptoms, including weight loss, exhaustion, slow gait speed, poor handgrip strength, and sedentary behavior (Fig. 4.4). The Fried frailty phenotype has been tested in surgical patients and shown to be associated with worse postoperative outcomes.[98] In the Cardiovascular Health Study, frailty was defined as three or more of these five criteria, prefrail state as one to two positive domains, and robust state as a score of zero. Other tools that measure slowness or low endurance as a manifestation of frailty, such as Timed Up & Go tool or grip strength, are also part of the phenotypic model.

NEW HORIZONS OF RISK ASSESSMENT

Use of Artificial Intelligence

Although the previous prediction models have been shown to provide accurate and usable risk estimates, these models were generally built under the presumption of linear and additive relationships between the preoperative variables. This notably does not take into account the interactions between variables, including synergistic or antagonistic effects. Because humans are complex beings, it is important to understand the global picture, rather than individual components. It has been suggested that application of machine learning and artificial intelligence technologies may be better suited to interpret the complex interactions between individual risk factors rather than linear regression models.

Current models often rely on established datasets such as the ACS NSQIP. However, these are limited by the availability of variables that traditionally were manually extracted. Harnessing the power of the totality of information contained in the electronic health record allows for the integration of all available clinical and surgical data and allots a massive amount of data for machine learning algorithms to learn from and be tested on. Initial studies demonstrate that machine learning models using datasets derived from an intuitional electronic health record can predict morbidity, mortality, and outcomes data such as length of stay more accurately than prediction models built from manually collected data.[99] However, the current structure of the electronic health record does not facilitate rapid transmission of data to machine learning models and applications. To address this, researchers at Duke developed a machine learning model, called *Pythia,* that uses a direct pipeline to the electronic health record to predict risk of postoperative complications and to classify patients according to this risk with high sensitivity and specificity.[100]

Limitations to the Pythia model are that it evaluates only invasive surgical procedures, does not account for patients with missing data, and necessitates variables that occur during surgery to make a final prediction, meaning it is not able to be used before surgery. In response, a group at the University of Pittsburgh Medical Center (UPMC) developed a gradient-boosted decision tree machine learning method for preoperative surgical risk prediction using only preoperative variables, and this tool is also able to oversee imputed values. The resultant tool is able to accurately identify patients who were at high risk of adverse outcomes using only preoperative variables within the electronic health record. When compared with the ACS NSQIP Surgical Risk Calculator, the model performed better, suggesting that using it may allow for individualized perioperative care and ultimately may be associated with improved outcomes.[101] This tool has successfully been implemented by the anesthesiology department at the UPMC. One of the advantages of the UPMC machine learning model is automated extraction of data from the electronic health record and the ability to find patterns in missing data to make a prediction. This makes the UPMC tool, and those with similar methodology, flexible and generalizable.

MySurgeryRisk was developed at the University of Florida with the goal of being universally applicable for any type of surgery, while using all available data within any electronic health record platform and by having the capacity for automation and implementation in a real-time clinical workflow. This group has developed an automated risk prediction system based on data routinely available before surgery, is universally applicable to any surgical context, and has the ability to handle any data type in an electronic health record. Additionally, as it is designed to produce a precise probability of risk, the thresholds for the high-risk group can be set at different operating points so that sensitivity and specificity can be tuned to match the requirements for specific clinical settings, such as high sensitivity for a screening setting.[102]

The ACS NSQIP Surgical Risk Calculator was updated in 2023 to use artificial intelligence–based algorithms. These have not yet been published or made available to the public. However, they require analysis of large volumes of data with each use of the risk assessment tool. This limits their portability. Another approach has been to develop logistic regression equations using machine learning applied to large electronic health record–based datasets, allowing them to be portable[103,104] for implementation in different health systems. The ASPIN [Automated Surveillence of Postoperative Infections] project to develop automated preoperative and postoperative assessment of surgical patient complications uses such an approach to predict individual patient probabilities of surgical complications, but it is not able to

TABLE 4.7 **Summary of Surgical Risk Assessment Tools**

NAME	ORIGIN	YEAR OF FIRST PUBLICATION	SOURCE DATA	NUMBER OF PREDICTOR VARIABLES	NUMBER OF OUTCOMES	MODEL TYPE	MODEL PERFORMANCE	VALIDATION
American College of Surgeons Surgical Risk Calculator	American College of Surgeons	2013	ACS NSQIP	21	8	Originally multivariable logistic regression; revised to machine learning	**Mortality**: c-statistic = 0.944, Brier score = 0.011 **Morbidity**: c-statistic = 0.816, Brier score = 0.069	Internal and external
Surgical Risk Preoperative Assessment System (SURPAS)	University of Colorado	2016	ACS NSQIP	8	16	Multivariable logistic regression	**Mortality**: c-statistic = 0.928, Brier score = 0.0115 **Morbidity**: c-statistic = 0.800, Brier score = 0.0918	Internal and external
9-Point Surgical Mortality Probability Model	Multi-institutional	2012	ACS NSQIP	3	1	Multivariable logistic regression	**Mortality**: c-statistic = 0.900	Internal and external
Pythia	Duke University	2018	EHR data	194	14	Machine learning	**Mortality**: AUC 0.916 (0.88, 0.95) **Morbidity**: AUC 0.836 (0.83, 0.85)	Cross-validation
MySurgeryRisk	University of Florida	2019	EHR data	285	8	Machine learning	**Mortality**: AUC 0.83 (0.81, 0.85)	Cross-validation

provide deterministic predictions or outcomes.[105] Research is ongoing regarding the use of natural language processing to add data from clinic and inpatient notes to risk prediction algorithms.

A summary of surgical risk assessment tools is shown in Table 4.7.

OUTLINE

Access to Care
Screening
Health Literacy
Health Behaviors
Trauma and Injury Prevention
Socioeconomic Factors
Racism and Discrimination
Interventions to Promote Equity
Conclusion

The World Health Organization defines social determinants of health (SDOH) as the "conditions in which people are born, grow, work, live and age and the wider set of forces and systems shaping the conditions of daily life. These forces and systems include economic policies and systems, development agendas, social norms, social policies, and political systems."[1] SDOH domains include economic stability, employment status, physical environment, and education access and quality as well as healthcare access and quality.[2] Further, patients' demographic characteristics shape the ways in which they may experience various SDOH domains. Demographic differences can result in SDOH-related disparities that are important to both the patients themselves and the healthcare professionals caring for them.

Along the perioperative continuum, spanning from making an appointment to consulting with a surgeon, to having an operation and finally recovering postoperatively, SDOH can affect the way that patients are able to interact with and benefit from the healthcare system. Surgeons can play a vital role in helping recognize, research, and advocate for change with regard to SDOH, with the goal of progressing toward surgical health equity. The relationship between SDOH domains and disparities in outcomes is clear; however, the interplay between these factors is complex.

To fully understand and effect change with regard to SDOH-related disparities, it is important to first understand how, when, and where SDOH most affect surgical patients throughout the perioperative period. In this chapter, we will describe how SDOH affect surgical patients and the role surgeons can play in mitigating SDOH-related disparities among patients.

ACCESS TO CARE

SDOH can have an enormous impact on basic access to medical care. Timely access to care is especially important in surgical patients, both in elective and emergency settings. Bouchard et al. found that pediatric patients from neighborhoods with lower educational levels and socioeconomic status were more likely to present with complicated appendicitis than simple appendicitis, suggesting a delay in care.[3] Similar findings have been observed in patients undergoing appendectomy,[4] cholecystectomy,[5] and colorectal surgery.[6] Williamson et al. found that patients with lower socioeconomic status were less able to access high-volume surgical centers—with their demonstrably better outcomes—compared with patients with high socioeconomic status.[7] Insurance status has a large role in access to screening and overall access: Ko et al. found that the majority of disparities seen among females with breast cancer being diagnosed at a later stage were associated with inadequate insurance coverage.[8] Notably, however, even in state and federal programs designed to facilitate equitable access, non-Hispanic Black females with breast cancer have been shown to have significantly higher rates of delay in diagnosis and delay in treatment initiation compared with White females.[9]

Telehealth services have become more widespread with the onset of the COVID-19 pandemic. This trend may have ameliorated some transportation-related barriers to care, but it also exacerbated baseline disparities in access secondary to differential access to reliable Internet and technologic devices, which also enable patients to view medical information via patient portals. Although smartphone ownership and Internet access have increased across all groups since 2019, disparities persist.[10,11] In general, older, less educated, and lower-income patients have more difficulty accessing online services,[10] a finding that has been borne out in studies of telemedicine visits as well. Patients who are older, non-English speaking, from lower-income backgrounds, and are Asian, Latinx, or Black are less likely to use video telehealth services.[12–18]

SCREENING

Cancer screening has been shown to decrease the morbidity and mortality associated with cancer by facilitating diagnosis of presymptomatic, early-stage disease.[19–23] However, access to and implementation of cancer screening is often negatively affected by differential SDOH experience. In breast cancer, for example, higher stage at diagnosis and worse overall survival have been associated with "poverty, lack of education, neighborhood disadvantage, residential segregation by race, racial discrimination, lack of social support, and social isolation."[24] Castro et al. found that patients with lower income and education have lower rates of screening for lung cancer and higher false-positive rates.[25] Transgender patients represent another vulnerable group that faces significant barriers to accessing breast cancer screening.[26]

Screening for benign disease processes is also affected by SDOH. With regard to abdominal aortic aneurysm (AAA) screening, Barshes et al. found that among patients in Texas, Black patients had lower rates of clinic visits and abdominal ultrasounds compared with White patients, and the majority of AAA repairs occurred in White patients.[27] Black patients and female patients with AAA have been shown to be more likely to be treated in an emergent setting, suggesting missed opportunities for identification of high-risk AAAs in the outpatient setting.[28,29]

HEALTH LITERACY

Health literacy is another important asset that patients need in order to navigate an increasingly complicated healthcare system. Personal health literacy is defined by the Centers for Disease Control and Prevention (CDC) as the "degree to which individuals have the ability to find, understand, and use information and services to inform health-related decisions and actions for themselves and others."[30] Health literacy can affect a patient's ability to access services or follow through on referrals or screening recommendations and also to comprehend an informed consent form before surgery and to follow discharge instructions. Diressens et al. found that after hepatobiliary surgery, patients with low health literacy had longer lengths of stay and higher rates of complications compared with patients with high health literacy.[31]

HEALTH BEHAVIORS

Smoking cessation, nutritional optimization, and glycemic control are important aspects of preoperative preparation for elective surgery. Poor nutrition, active smoking, and poor glycemic control in the preoperative period has been associated with myriad postoperative complications as well as prolonged recovery after surgery.[32–38] In general, patients who are female, with lower socioeconomic status, and with lower levels of educational attainment are less likely to attempt to and successfully quit smoking.[39] Black individuals are less likely than non-Hispanic Whites and Hispanic individuals to successfully quit smoking.[39,40] Additionally, Perez et al. found that Black and Hispanic patients with cancer are underrepresented in trials to address tobacco cessation, which limits generalizability of known techniques to patients in these groups.[41] Unsurprisingly, patients who have a lower socioeconomic status or live in rural areas are also more likely to have food insecurity,[42] which has been associated with rates and management of type 2 diabetes mellitus and ultimately on patients' ability to maintain adequate glycemic control.[43]

TRAUMA AND INJURY PREVENTION

A number of SDOH domains, such as safety or economic stability of a physical environment, can influence a patient's risk of traumatic injury. These types of injuries represent preventable harm that merit further study and legislation to effect broad impact. One example is the risk of violent injury. As an example, children from socioeconomically disadvantaged backgrounds had higher rates of firearm-related injuries, motor vehicle–related injuries, and violence-related injuries.[44] In a review of patients presenting to an urban academic trauma center with gunshot wounds to the head, "assault-related gunshot wounds to the head were more likely to involve Black or Latinx men of lower socioeconomic status" compared with White males.[45] Additionally, Bailey et al. found that "Black men are 2.5 times more likely to be killed by police than white men, Native American men 1.5 times, and Latino men 1.3 times more likely. Black women are 1.4 times more likely than white women to be killed by police,"[46] and Price et al. showed that 23% of all law enforcement officer killings using firearms in the United States involved non-Hispanic Black Americans during 2011–20.[47]

SOCIOECONOMIC FACTORS

Socioeconomic factors represent a component of SDOH that can exert some of the most significant effects on postoperative quality metrics such as hospital readmission rates.[48] In a review of patients with hypertrophic pyloric stenosis, Gilna et al. found that babies from low-income families had higher rates of readmission compared with higher-income families.[49] Patients with low health literacy as well as low home social support and connectivity have been shown to have significantly higher rates of unplanned readmission rates after major surgery.[50–52]

The Social Vulnerability Index (SVI) was created by the CDC using US census demographic variables to quantify patients who may need additional support.[53] Studies have shown that higher levels of social vulnerability were associated with worse surgical outcomes[54] and higher rates of 30-day mortality, postoperative complications, and readmissions.[55] Azap et al. had similar findings in patients undergoing hepatic resection; among patients with the same insurance coverage, patients who had higher levels of social vulnerability were found to have worse outcomes, including higher rates of complications and mortality.[56] Dalmacy et al. found that among patients who underwent hepatopancreatic surgery, those with high social vulnerability were more likely to receive fragmented postoperative care, defined as readmission to a hospital different from the index surgical institution.[57] Williamson et al. observed that patients with lower socioeconomic status had higher rates of in-hospital mortality and complications compared with patients with higher socioeconomic status, independent of whether they were treated at a high-volume surgical center.[7] Finally, socioeconomic differences can also translate into disparities in morbidity and mortality. Jerath et al. found that patients with a lower socioeconomic status lived fewer days after noncardiac surgery.[58]

RACISM AND DISCRIMINATION

Notably, exposure to prejudice, bias, and overt racism are SDOH domains that are differentially experienced by racially and ethnically minoritized individuals, leading to disparities even in circumstances of economic parity. Willer et al. demonstrated that pediatric patients from families with lower socioeconomic status had significantly higher rates of postoperative mortality, and Black children had higher postoperative mortality compared with White children, even when controlling for socioeconomic status.[59] Non-Hispanic Black females are more likely than White females to be diagnosed with triple-negative breast cancer, which is associated with an overall worse prognosis and poor response to hormone-based therapies.[60] Notably, however, although Black females with breast cancer have a 40% higher mortality rate compared with White females,[61–63] most of the Black-White breast cancer mortality difference can be attributed to differential survival from estrogen receptor–positive breast cancer (i.e., the least aggressive subtype for which we have some of the most established therapy).[64] Similar trends have been observed after coronary artery bypass surgery, where Black females have higher odds of postoperative mortality compared with White males.[65] Among patients with lung cancer, Black males have the highest incidence and mortality of any racial/ethnic group even when controlling for smoke exposure. They are also more likely to present at a later stage and to be diagnosed at a younger age.[66]

Although differences in baseline rates of biologically aggressive disease play a small part in observed racial and ethnic differences in surgical outcome, most of the racial disparities observed in surgical outcomes are believed to be the result of the individual and systemic bias experienced by minoritized patients, often manifesting in the form of trauma and inadequate care. Black patients are more likely than White patients to be treated without pain medications by emergency medical services (EMS),[67] are more likely to be transported to safety-net hospitals,[68] and are more likely to be undertriaged when severely injured.[69] Black and male trauma patients have the highest rates of mortality in the United States.[70] Similarly, among pediatric penetrating trauma patients, Hispanic and Black patients had higher mortality rates compared with White patients.[71]

INTERVENTIONS TO PROMOTE EQUITY

Mitigation of SDOH-related disparities and promotion of equity can be accomplished only with evidence-based, multilevel interventions and need to include partnerships between patient advocates, researchers, community stakeholders, government policymakers, health systems, and public health officials. Addressing patient-specific disparities alone will not achieve health equity.

An important first step will be assessing the scope of the problem for specific diseases and within defined geographic locations to facilitate referring patients to appropriate services. Surgeons can begin to do this at the individual level with their own patients by taking a thorough social history to include screening for social risk and unmet social need with regard to various SDOH. Currently, patients are screened for other preoperative needs, such as risk assessment and optimization by a cardiologist or pulmonologist. Assessing for patient needs around their SDOH should be performed in a similarly systematic and routinized way. Despite being increasingly integrated into electronic health records (EHRs), SDOH documentation is performed by few providers at patient visits.[72–74] Documenting SDOH and responding to unmet social need within existing EHR pathways must be prioritized at both the provider and health-system level by, for example, integrating prompts for referrals to appropriate (and available) services within the EHR.

To have generalizable information about the natural history of disease and the efficacy of novel treatments and technologies, clinical trials need to have adequate representation of marginalized populations. White patients continue to be overrepresented in clinical trials for cancer treatment.[75–79] Researchers have sought to mitigate these disparities in representation by encouraging techniques such as equity-focused investigator training, community buy-in and engagement, advertising studies using trusted community sources, encouraging institutional commitment to equitable patient recruitment, and engaging clinical trial navigators.[80–84]

Further, there needs to be an increased focus on community-based participatory research (CBPR) as it relates to barriers to accessing surgical care. CBPR has been shown to be an effective investigative approach through which researchers partner with underserved communities to elucidate factors that may contribute to disparate outcomes and to prioritize research viewed as important by community members.[85,86] Regardless of discipline, researchers can use CBPR techniques to shed light on lived experiences and disparities related to myriad factors that affect surgical patients such as gun violence, organ transplantation, or cancer screening.

Adding or expanding patient navigator services at the hospital level can significantly affect patient outcomes. Mohan et al. found that intervening on SDOH to improve breast, cervical, and colorectal cancer screening was cost-effective, associated with earlier diagnosis and treatment, improved health outcomes, and improved quality-adjusted life years.[87] These interventions included developing patient navigator programs to provide patient support and improve quality of care and increase rates of cancer screening as well as programs to leverage principles of behavioral economics.[88,89]

At the policy level, expanding access to healthcare, such as Medicaid expansion, has been associated with improved care for cancer patients.[90] Similarly, Le Blanc et al. found that Medicaid expansion was associated with a reduction in late-stage diagnosis of breast cancer.[91] The enactment of the Affordable Care Act in 2010 has been shown to have increased insurance coverage, patient access to cancer care, and gender-affirming surgery and has had a positive impact overall on cancer and surgical outcomes among vulnerable patient populations.[92–96] Additionally, the recent 2022 Supreme Court decision to overturn *Roe v. Wade* has exacerbated geographic and socioeconomic disparities in access to safe abortions.[97–100] Further, state and federal firearm regulations have significant effects on the accessibility of firearms and ultimately on gun-related deaths.[101–103]

CONCLUSION

In summary, SDOH have a significant impact on the care of surgical patients throughout the entire trajectory of surgical care. Surgeons can identify opportunities for intervention and improvements in health equity for all populations in collaboration with fellow clinicians, researchers, policymakers, and patients themselves to promote equitable surgical care and optimize surgical outcomes for the patients we are privileged to treat.

CHAPTER 6

Critical Assessment of Surgical Outcomes and Health Services Research

Benjamin S. Brooke, Rachel A. Greenup, and Alex Bernard Haynes

OUTLINE

Evidence-Based Approach to Surgery
  Evaluating Scientific Evidence in Clinical Practice
  Study Design
  Synthetic and Systematic Outcome Studies
Appraising Surgical Evidence
  Evaluating Study Quality
Interpreting and Applying Evidence to Surgical Practice
Conclusion

The practice of surgery has undergone a dramatic evolution over the past century, with the availability of new scientific evidence supporting the use of different surgical techniques and management. Central to this mission is the process of critically appraising the surgical evidence base at every opportunity and deciding what can and should be applied to routine clinical practice.

Critical appraisal is defined as the process of carefully and systematically examining research evidence to judge its validity, its value, and its relevance to a particular context.[1] Decisions related to surgical care delivery should be made after a careful assessment of individual patient preferences, clinical experience, and critical appraisal of the evidence in the medical literature. However, given the breadth and complexity of information, surgeons often are challenged to critically evaluate the literature and extrapolate the findings from health services and outcomes studies.

This chapter provides a framework to critically appraise surgical outcomes and health services research. This includes methods to assess the strength of evidence for surgical practices, establish the validity of scientific studies in surgery, and apply evidence-based medicine practices to improve the quality of surgical care. The intent is to provide the reader with conceptual and analytic tools that a modern, evidence-based surgeon needs to navigate the surgical outcomes literature and implement practices that are based on sound science, with a broad overview of research methods that may inform original science.

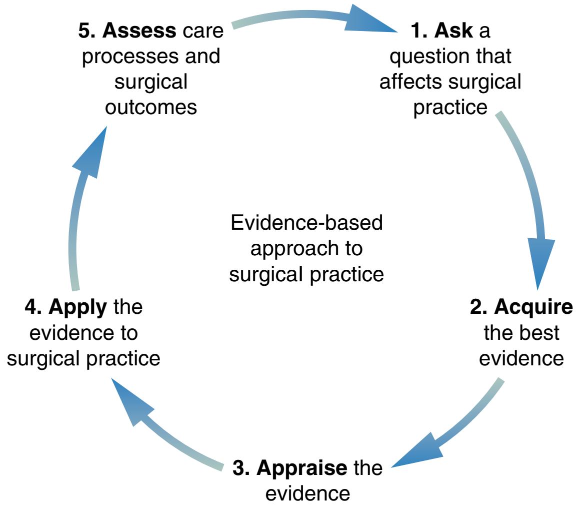
EVIDENCE-BASED APPROACH TO SURGERY

Surgeons must be able to understand the evidence-based medicine process in order to identify, access, apply, and integrate new knowledge into their clinical practice and provide high-quality care for their patients. In practice, evidence-based medicine involves the following three fundamental principles.[2] First, the ability to make optimal clinical decisions requires awareness of the best available research evidence. Second, there must be standards by which to judge whether evidence can be trusted. Third, the quality of evidence for benefit must be weighed against the risks, burdens, and costs associated with alternative management strategies, while simultaneously considering individual patients' predicaments, values, and preferences. This evidence-based approach to clinical practice can also be remembered by the five As—ask, acquire, appraise, apply, and assess (Fig. 6.1).[3] These five steps provide a model for practicing evidence-based medicine that all clinicians are encouraged to use to drive optimal care delivery and decision-making.

In the practice of surgery, evidence-based medicine can influence factors ranging from the indications for procedures, comparative effectiveness of different management approaches, and other issues related to the delivery of surgical care. For example, a surgeon who learns of a new procedure or technique may seek to identify evidence to inform a decision about incorporating this into their practice. The next step is to determine whether any research studies provide evidence that supports the efficacy and effectiveness of that new procedure. For a study to provide a high level of evidence, it needs to address a significant clinical problem and provide novel results, extend what was previously known, or describe an innovative procedure that represents an improvement over existing technique. The study should include patients who are likely to be offered the intervention in everyday surgical practice. Moreover, it should focus on surgical treatments or strategies that can be replicated in a real-world clinical setting.

Evaluating Scientific Evidence in Clinical Practice

Surgeons can use several strategies to review the literature, evaluate research study questions, and determine whether scientific evidence should be applied to their clinical practice. One strategy for evaluating the implications of a research question is the PICOT framework—population, intervention, comparison, outcome, and time frame (Table 6.1).[4] PICOT is a structured way to summarize the main components of scientific evidence and can also be used to appraise a study or interpret its results.[5] For example, a surgeon evaluating a surgical outcomes study would be prompted to ask: (P) Is the study population or clinical problem comparable with surgical



5. Assess care processes and surgical outcomes
1. Ask a question that affects surgical practice
Evidence-based approach to surgical practice
4. Apply the evidence to surgical practice
2. Acquire the best evidence
3. Appraise the evidence

FIGURE 6.1 The evidence-based approach to clinical practice.

TABLE 6.1 **PICOT Framework for Evaluating Research Questions**

ACRONYM	ELEMENT DEFINITION	DESCRIPTION
P	Population or problem	Sample of subjects or problems that will be addressed.
I	Intervention	What is being tested in the study? May apply to therapy, prevention, diagnosis, or exposure groups.
C	Comparison	What is the main intervention being compared with?
O	Outcome	The main results that are being examined and assessed.
T	Time frame	Time for data collection and follow-up assessment.

patients or issues that I deal with in routine clinical practice; (I) Is the intervention truly novel, and does it represent an improvement over current standards of care; (C) Are study comparators valid and representative of usual care; (O) Are outcome measures valid and reliable; and (T) Does the duration of treatment and follow-up correspond to the duration important to patients? The PICOT framework provides a systematic process for determining whether studies are valid and relevant to clinical practice.

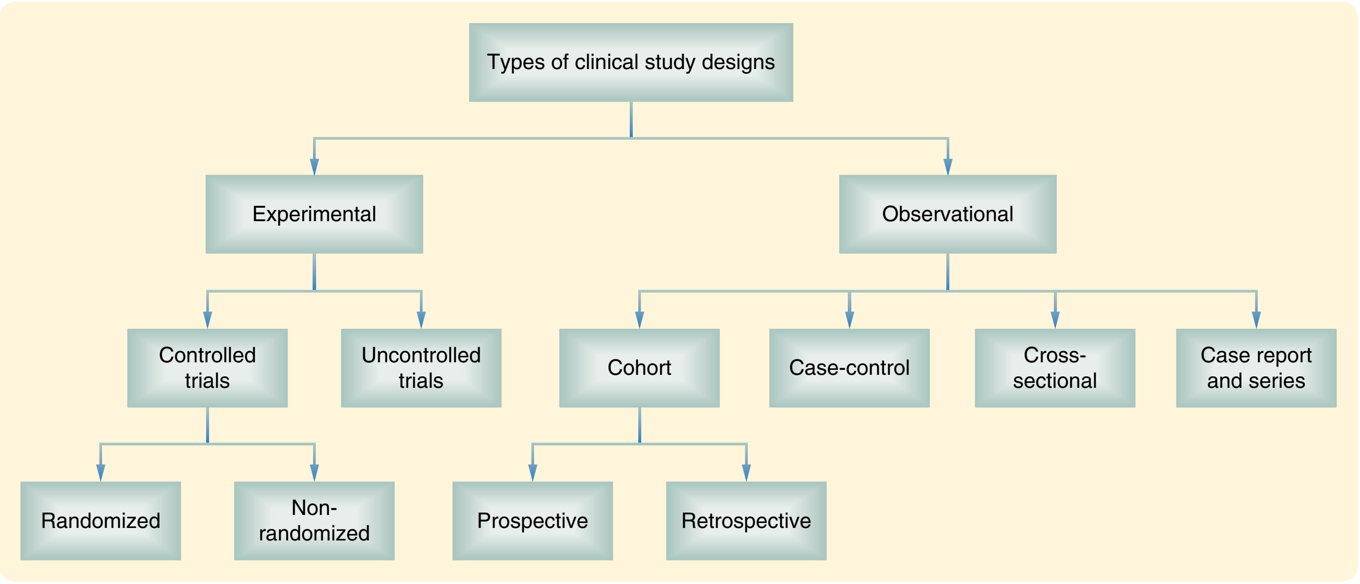
Study Design

Many study designs are used to undertake surgical research, including both experimental and observational designs (Fig. 6.2). The specific study design used to generate evidence is often influenced by practical considerations, such as resource availability and feasibility. Nonetheless, the study design selected to evaluate surgical interventions will largely determine our levels of confidence about cause and effect.

Several criteria have been proposed to establish epidemiologic evidence of causal relationships, including the set of nine criteria originally published by Sir Bradford Hill in 1965.[6] Distilled down to the most simplistic terms, causal relationships exist when (1) the cause precedes the effect, (2) the cause was related to the effect, and (3) we can find no other plausible explanation for the effect other than the proposed cause.[7] Experimental studies that are prospective and randomized usually provide the greatest insurance that these criteria are met and are associated with the highest levels of evidence. But even prospective randomized studies can lead to erroneous conclusions if they are not executed or analyzed properly. Evaluating the quality of clinical evidence requires a close look at the strengths and limitations of each type of study design (Table 6.2).

Randomized Controlled Trials

When appropriately designed and conducted, randomized controlled trials (RCTs) are considered the gold standard for evaluating most types of healthcare interventions. In this study design, patients are randomly allocated to either a treatment or a control group before receiving an intervention, using an element of chance to determine the assignments, similar to



Types of clinical study designs
Experimental
Observational
Controlled trials
Uncontrolled trials

TABLE 6.2 **Strengths and Weaknesses of Common Study Designs Used in Clinical Research**

STUDY DESIGN	CHARACTERISTIC	STRENGTHS	WEAKNESSES
Randomized controlled trial	Allocation of subjects to experimental or control group by chance	• Ability to establish causal effects between exposure and outcomes • Can study more than one intervention	• Expensive • Can take a long time • Not suitable for rare events • Often low generalizability because of selection criteria
Cohort study	Cohort of subjects is compared based on different exposures	• High generalizability • Can study rare exposures and multiple outcomes	• Some potential to establish causal effects • Can take a long time (prospective) • Selection bias • Can be expensive
Case-control study	Cases are compared with controls with respect to exposure	• Can study rare outcomes and multiple exposures • Relatively inexpensive • Hypothesis generating	• Selection bias • Recall bias • Limited potential to establish causal effects • Can only study one outcome
Cross-sectional study	Exposure and outcomes measured at same point in time	• Use for describing disease prevalence • Fast and inexpensive • Hypothesis generating	• Sample bias • Survival bias • Very limited potential to establish causal effects
Case series and report	Detailed description of one or more subjects (i.e., cases) without a control group	• Very detailed • Inexpensive • Hypothesis generating	• Selection bias • Not generalizable • No ability to establish causal effects

tossing a coin. After randomization in a parallel design, patients are followed in exactly the same way, and the only difference is the assigned treatment group. However, patients can be exposed to more than one intervention in an RCT with a factorial or cross-over design.

The RCT study design has the greatest potential for determining causation between exposure and outcome given that randomization balances both known and unknown prognostic factors (i.e., measured and unmeasured confounders) between comparison groups during the assignment of treatment. As such, the effect of the treatment on outcomes relative to the control group can be determined while other variables are kept constant and selection bias is minimized. Furthermore, randomization can facilitate blinding (also known as *masking*) of the identity of treatments from investigators, participants, and assessors.

RCTs can be used to compare nearly all types of interventions used in surgical patients. This includes surgical procedures, medications used before or after surgery, screening programs, or diagnostic modalities, to name a few. But although RCTs help us determine the presence and strength of a causal relationship between different surgical interventions and a given outcome, they also have several weaknesses. First, they are expensive to complete, and it can take many years to obtain results when large sample sizes are needed. Second, the results may not be generalizable to patients in everyday practice because of narrow enrollment criteria and may bias against populations historically marginalized by the healthcare system. Third, many surgical interventions are not easily amenable to randomization, either through difficulty with blinding, ethical concerns about "placebo" surgery, or patient unwillingness to have treatment determined through the process of randomization. Finally, RCTs can still yield biased results if the study is not well designed or executed properly and lacks methodologic rigor.

To assess whether RCT findings are valid, surgeons need complete and transparent information on the methodology and results. This need for adequate RCT reporting fueled the development of the original Consolidated Standards of Reporting Trials (CONSORT) statement in 1996 and its subsequent revision in 2010.[8,9] The most recent CONSORT statement includes a 25-item checklist and flow diagram, which provides guidance for reporting all types of RCTs but focuses on the most common two parallel group design types. This checklist provides an easy way for surgeons to evaluate the quality of evidence derived from these types of studies.

Cross-Sectional Study

A cross-sectional study involves looking at research subjects who differ on one key characteristic at a specific point in time. Exposure and outcome data are collected at the same time point among subjects who are similar in most other characteristics but different in a key factor of interest. For example, this could involve patients undergoing a specific type of surgery who come from different age groups, income levels, or geographic locations.

Cross-sectional studies are commonly used to describe disease prevalence or characteristics that exist in a community or hospital setting. This study design is inexpensive and is often used to make inferences about possible relationships or to gather preliminary data to support further research and experimentation (i.e., hypothesis generating). However, these studies are limited by survival bias and cannot analyze associations longitudinally or determine causal relationships between exposure and outcome variables. Furthermore, there may be a sampling bias if the timing or selection strategy of the cross-sectional study leads to a sample that is not representative of patients in the general population.

Case-Control Study

The case-control design uses a different sampling strategy in which the investigators identify a group of individuals who exhibit a specific outcome (i.e., the cases) and then compare this group to a set of individuals who do not exhibit the outcome of interest (i.e., the controls). The cases and controls are then compared with respect to the frequency of one or more past exposures. If the cases have substantially higher odds of exposure to a particular factor compared with the control subjects, it suggests an association but does not necessarily provide evidence of causal inference.

Case-control studies have numerous strengths. This study design allows investigators to examine risk factors associated with outcomes that are uncommon, to examine the association of multiple risk factors with outcomes simultaneously, and to examine outcomes that occur a long time after the exposure occurs. They are also relatively inexpensive to complete and can help generate hypotheses. On balance, however, case-control studies are limited by their retrospective design that allows the potential for recall and selection bias. Moreover, identifying valid control groups to compare to cases can be difficult, estimating the frequency of exposure in the population at large is often inaccurate, and the design allows evaluation of only one outcome at a time.

Cohort Study

A cohort study is an observational study design in which groups of subjects are identified based on their exposure to a particular risk factor and then compared with a group that has not been exposed to that same factor. This study design can be conducted from either a forward-looking (i.e., prospective) or backward-looking (i.e., retrospective) viewpoint. Prospective cohort studies are planned in advance and carried out over time to assess outcome incidence among exposure groups. In comparison, retrospective cohort studies look at data that already exist and attempt to identify risk factors for outcomes that have already occurred. Retrospective analyses of existing surgical databases, in particular, constitute one of the most common applications of this study design.[10] For both types of cohort studies, a higher incidence of outcomes in the exposed group suggests an association between that factor and the outcome. However, because prospective studies collect information about exposures and outcomes purposefully and systematically, they provide stronger evidence for causation.

Cohort studies have several strengths and limitations. The advantages of cohort studies are that they are easier and less expensive to conduct than RCTs, the incidence (or rate) of exposure and outcomes can be estimated, and subjects in cohorts can be matched to limit the influence of confounding variables. In addition, enrollment criteria and outcome measures can be standardized, and—unlike case-control studies—multiple simultaneous outcome assessment is possible. However, cohort studies also have several disadvantages. Because there is no randomization, one cannot account for unmeasured imbalances in patient characteristics. Blinding or masking is difficult (or impossible retrospectively), and outcomes of interest can take a long time to occur, requiring many years of information about exposures. For retrospective studies in particular, treatment selection bias and confounding variables may lead to unmeasured differences in exposure groups over time that cannot be controlled for within statistical analysis. Moreover, interpretations can be limited because of missing data that are impossible for researchers to go back in time to collect.

To assess the evidence quality derived from different types of cohort studies, several simplified checklist methods have been developed. The Strengthening the Reporting of Observational Studies in Epidemiology (STROBE) statement is one of these checklists that provides an organized system for assessing observational study methodology and results that is similar to the CONSORT system used for RCTs.[11] STROBE provides guidance on how to report critical components of research studies from all types of observational study designs, including cohort, case-control, and cross-sectional study designs.

As part of a series of articles on research methods published in a special issue of *JAMA Surgery* in 2018, another checklist was proposed for evaluating the quality of evidence derived from databases commonly used in surgical outcomes research.[10] This checklist consists of 10 items for review that can be used when evaluating the findings of retrospective cohort studies or considering questions that might be reasonably addressed using these databases. Most notably, this includes ensuring the database is well-matched to a focused research question of interest and that missing data are addressed through the statistical analysis, including imputation or sensitivity analyses. In the same issue of *JAMA Surgery*, in-depth information was provided for 13 of the most popular surgical databases, including the National Inpatient Sample (NIS); Surveillance, Epidemiology, and End Results (SEER) Program[12]; Medicare Claims[13]; National Surgical Quality Improvement Program (NSQIP)[14]; Society of Vascular Surgery Vascular Quality Initiative (SVS-VQI)[15]; and the Society of Thoracic Surgeons (STS) National Database.[16]

Understanding the strengths and weaknesses of different data sources is essential to interpret findings and assess evidence quality. Some of these datasets use prospectively collected clinical data extracted by clinical reviewers (e.g., NSQIP, SEER, SVS-VQI, STS), whereas others use administrative claims data (e.g., NIS, Medicare) collected for insurance purposes. How data are collected affects the conclusions that can be made and the types of questions that can be appropriately answered. Other factors to consider include whether a dataset tracks only an index episode or can account for care delivered or complications occurring outside of the initial hospitalization; whether the dataset is a sample or complete registry, thereby altering any epidemiologic conclusions; whether the patients included in the dataset are reflective of the broad community of surgeons or only more specialized centers participating in a registry; how data variables are defined in relation to clinical care; and finally how accurately the data included are ascertained. These factors all affect the conclusions of the study and the generalizability of the findings to any given population.

Case Series and Reports

Historically, the surgical literature has relied on case series and case reports to describe surgical interventions and patient outcomes. These have been the most highly cited type of study design in the surgical literature until the past couple of decades.[17] Observations are made on a series of individuals, usually all receiving the same surgical intervention, but with no control group. The sampling of a case series is based on either exposure or outcomes, but not both. For example, a series could include all patients who underwent surgery at a single institution over a decade, or a case report might describe patients who experienced some rare adverse event after surgery.

The strength of case series and reports lies in their ability to provide both an in-depth narrative and granular clinical information on a given topic when other study designs cannot be carried out. This in turn may help to generate new hypotheses. However, the main limitation of this study design is the lack of ability to generalize findings or to establish a causal relationship between exposures and outcomes. Case series and reports cannot be comparative, and no absolute risk or relative effect measures for an outcome can be calculated. As such, studies with these designs are nearly always considered low-quality evidence.

Synthetic and Systematic Outcome Studies

Meta-analyses

One of the highest forms of evidence quality comes from a meta-analysis, in which the results from multiple studies on the same topic are combined. This includes data generated from either experimental or observational study designs (see Fig. 6.2). The basic tenet behind meta-analysis is that there is an underlying true association between an exposure and outcome variable assessed within similar studies but which has been measured with a certain degree of error within each individual study. By combining similar outcomes studies and using statistics to derive a pooled estimate, meta-analysis can improve the precision and accuracy of this estimate and have the statistical power to detect the true association. Furthermore, meta-analyses allow study results to be generalized to larger populations, permit inconsistency of results between studies to be quantified and analyzed, and identify the presence of publication bias between similar studies.[18]

However, several factors can limit the quality of evidence derived from meta-analyses.[19] Often, studies examining a specific topic do not have comparable patient populations, end points, or exposure groups. Excess variation or heterogeneity in exposure or outcome variables between individual studies beyond what chance alone would predict indicates that the results of the studies are not compatible and should not be pooled. This is a particular concern when aggregating results from observational studies in which selection bias and confounding may have affected the original analysis. Notably, changes in clinical practice over time may affect patient outcomes that are unrelated to the intervention of interest and need to be addressed. Moreover, the evidence derived from a meta-analysis is only as good as the methodology of the studies that are included. Even a well-designed meta-analysis cannot correct for poor study design or intrinsic bias that was present when the included studies were originally designed or analyzed.

Cost-Effectiveness Analysis

A cost-effectiveness analysis is an economic evaluation that simultaneously measures the outcomes and costs of alternative interventions. This type of research evidence has become increasingly prevalent in the surgical literature as health policy has increasingly focused on containing surgical costs and defining high-value care. Cost-effectiveness refers to analyses that directly compare the costs of one intervention with some other alternative intervention relative to the difference in clinical benefit. This ratio of differential costs to differential benefits is known as an incremental cost-effectiveness ratio (ICER).[20] The ICER is calculated by taking the ratio of the incremental cost (the difference in cost between two strategies) and the incremental effectiveness (the difference in outcomes between two strategies). For example, if intervention A is both more costly and more effective than intervention B, the ICER conveys how much it would cost to produce the incremental increase in effectiveness achieved by choosing intervention A over intervention B.

Effectiveness outcomes in cost-effectiveness studies are often assessed using the quality-adjusted life-years (QALYs) metric, which measures both the quantity and quality of life.[21] The QALY is constructed by weighting the amount of time spent in a health state by the quality of life in that health state. QALYs have been used extensively in surgical outcomes studies to assess different disease states, and healthcare strategies that cost less than $100,000 per QALY are generally considered to be cost-effective by current accepted standards.[22] For example, in one study, the ICER for coronary artery bypass surgery versus percutaneous coronary intervention for coronary artery disease was calculated to be about $30,000 per QALY gained.[23] As such, coronary artery bypass surgery is deemed by this evidence to be more cost-effective than percutaneous coronary intervention for coronary artery disease. Studies that use a general measure of benefit that considers the qualitative value of health (e.g., QALY) are typically referred to as cost-utility analyses.

Cost-effectiveness and cost-utility studies can help surgeons make clinical decisions by presenting cost and outcome trade-offs between competing interventions. These trade-offs can be simulated over time under different conditions using Markov models that incorporate estimates of risk (often from existing literature) of adverse events and probability of desired outcomes, such as cure, improved function, or longevity. Markov models assume that a patient is always in one of a finite number of discrete health states, each with a specified value and/or cost, and can transition from one health state to another over time based on known or estimated probabilities of events. By modeling the time dependence of probabilities for entering several different health states and outcomes, Markov models allow for many different scenarios to be estimated for any given clinical decision and are thus a valuable and versatile method for modeling the trade-offs between competing strategies.

Systematic Reviews

Beyond aggregation of data within meta-analyses, systematic reviews of outcomes research are another important means used to synthesize and organize bodies of surgical evidence.[18] Systematic reviews start with a question or hypothesis and involve a systematic search of the surgical literature using explicit criteria for selecting studies to answer the research question. This typically begins by developing a comprehensive and detailed search strategy, a priori, that can be used to identify, exclude, evaluate, and synthesize results from all relevant studies on a given topic. Once a search strategy is developed, it can be executed using several online databases including MEDLINE (National Library of Medicine database), EMBASE (medical and pharmacologic database by Elsevier Publishing), CINAHL (Cumulative Index to Nursing and Allied Health Literature), and the Cochrane Library. In comparison to informal or narrative reviews of the literature, the methods used by systematic reviews for evaluating studies and extracting information from them are rigorous and intended to reduce the potential for subjectivity or bias in the findings. Furthermore, systematic reviews are reported in a manner that is conducive to replication of both methodology and findings.

Well-conducted systematic reviews can be an invaluable resource for surgeons given the large and increasing volume of published studies each year on any given surgical topic. They can identify high-quality evidence within the literature and help define the exact knowledge base on any given subject. The Cochrane Library (https://www.cochranelibrary.com/cdsr/reviews), in particular, provides a large database of systematic reviews on a wide range of topics that affect surgical patients. By critically examining individual research studies, systematic reviews can help identify inconsistencies among different sources of evidence. Finally, these types of studies also help inform whether research findings can be applied to specific subgroups of surgical patients. For example, systematic reviews have been useful for defining the types of high-risk surgical patients who benefit most from perioperative β-blockers and those who have increased risk of adverse side effects from these medications during the postoperative period.[24]

Qualitative Data Analysis

Another important form of surgical research evidence is derived from qualitative data analyses. Qualitative data (also known as *descriptive data*) are nonnumerical empirical information collected by researchers to describe concepts, opinions, or interpretations of a specific topic. These data are typically captured from interviews, focus groups, document analysis, stated preference research, or notes taken during an observation. Analyzing these forms of qualitative data can reveal consistent patterns or themes among patients, providers, or other research subjects. These analyses may generate hypotheses that can be further tested with quantitative methods or clinical trials or, alternatively, help researchers drill down to better understand the findings from quantitative outcomes studies.

Several different methodologies are commonly used to conduct qualitative data analyses, including phenomenology, content analysis, grounded theory, and ethnography.[25] The goal of phenomenology is to study how individuals derive meaning from their life experiences by understanding how they perceive a specific phenomenon. For example, the long-term quality of life among patients who had undergone primary leg amputation for trauma could be studied this way. Content analysis is another method whereby documents such as interview or focus group transcripts are analyzed to determine frequencies and patterns of words in the textual data. Based on how materials are categorized, researchers can make inferences about common messages or themes within the text. In comparison, grounded theory methods are used to collect descriptive data when researchers want to develop new theories about how processes occur. Finally, ethnography is used to understand the norms, values, and social structures of groups, primarily through observation combined with focused interviews of participants.

The need for these types of qualitative research methods in surgery is recognized because they provide a deeper and richer understanding of the social and environmental contexts underlying surgical outcomes.[26] The strength of qualitative data analyses rests in their ability to shed light on phenomena that would be nearly impossible to study using quantitative methods alone. For example, grounded theory and ethnography methods have been used to understand operating room workflow or communications among surgical teams practicing in high-volume versus low-volume hospitals and to generate theories surrounding how information is exchanged between surgical and primary care teams during transitions of surgical care.[27] The opinions and experiences of surgeons, nurses, and trainees were solicited using these methods along with the ability to directly observe care processes and the technology used during communication. Alternatively, content analysis has been used to explore psychosocial issues related to surgery from patient focus groups, including reasons underlying satisfaction with care or problems that patients perceive as impeding high-quality care during episodes of surgical care.[28] Qualitative analyses allow for the assessment of patient-reported lived experiences without predetermined framing from research investigators. Notably, the quality of these data depends in part on how it is obtained; leveraging third-party interviewers that are relatable to study participants minimizes investigator bias and acquiescence bias (participants agreeing with what they believe the interviewer wants to hear), allowing for the greatest chance of eliciting unbiased data.

These different types of qualitative methods can also be combined with quantitative approaches in what is known as *mixed-methods research*.[29] Mixed-methods research involves collecting and analyzing both qualitative and quantitative data within the same study. Rather than focus on just one approach, mixed-methods studies allow investigators to define a specific research problem and then use a combination of methodologies in order to elucidate the relevant issues in a broader and more detailed fashion. For example, a recent mixed-methods research study looking at provider compliance with surgical safety checklists first analyzed provider usage of a checklist within an institution (i.e., qualitative analysis) and then interviewed providers to explore and contextualize the specific reasons for their checklist use as opposed to noncompliance (i.e., quantitative analysis).[30]

APPRAISING SURGICAL EVIDENCE

The evidence supporting surgical decision-making comes in many diverse forms. At one end of the spectrum, evidence is simply based on the empirical impression that a specific practice makes physiologic sense and seems to work well. Much of what surgeons do in daily clinical practice falls into this category and has not been formally tested. But at the other end of the spectrum, evidence has accumulated from multiple well-designed and conducted RCTs with consistent and reproducible results. The task of the evidence-based surgeon is to judge the reliability of scientific evidence and select practices that conform to the best available evidence.

Several different rubrics have been created to evaluate and determine study hierarchies or levels of evidence. These systems provide a method to judge the strength of scientific evidence, ranging from sources that are most reliable to those that are least sure. Although it is understood that not all surgical practices can be subjected to the highest levels of scientific scrutiny, surgeons are advised to base as many of their practices as possible on evidence gleaned from studies at the high end of the evidence hierarchy. This process is aided by several established systems for grading evidence.

One established hierarchy is the "levels of evidence" system popularized by the United States Preventive Services Task Force (USPSTF).[31] The USPSTF assigns evidence certainty at one of three levels—high, moderate, and low—on the basis of six critical appraisals and has become part of the vernacular for clinicians across all medical specialties. Well-designed and well-conducted RCTs are frequently referred to as *level 1 evidence*. When the USPSTF system was originally released, there was debate, given that the system simply identified the design of the study from which the evidence was drawn but did not describe important factors that influence the quality of evidence.[32] For example, a randomized double-blind placebo-controlled trial with 20,000 subjects would be awarded the same grade in the USPSTF system as an unblinded randomized trial with 50 subjects. And the latter trial would, in turn, be graded higher than a well-designed, multi-institution, prospective cohort study with 10,000 subjects. In response to these criticisms, changes were subsequently made to the USPSTF grading system in 2012 to account for factors other than study design, such as quality, consistency, and completeness.[33]

Another system for grading evidence that takes into account study quality and consistency was developed by The Grading of Recommendations Assessment, Development and Evaluation (GRADE) working group (Table 6.3).[34,35] GRADE has developed a structured scoring process for determining whether evidence should be downgraded or upgraded based on different study characteristics. For example, a multicenter RCT executed with poor allocation concealment and high attrition would be downgraded

TABLE 6.3 The GRADE System—Quality of Evidence and Strength of Recommendation

QUALITY OF EVIDENCE	DEFINITIONS	STRENGTH OF RECOMMENDATION	EXPLANATION
High	We are very confident that the true effect lies close to that of the estimate of the effect. Further research is very unlikely to change confidence in the estimate of effect.	Strong	Many high-quality trials confirming the effect
Moderate	We are moderately confident in the effect estimate. The true effect is likely to be close to the estimate of the effect, but there is a possibility that it is substantially different. Further research is likely to have an important impact on our confidence in the estimate of effect.	Conditional	Uncertainty about the balance between desirable and undesirable side effects
Low	Our confidence in the effect estimate is limited: The true effect may be substantially different from the estimate of the effect. Further research is very likely to have an important impact on our confidence in the estimate of effect.	Conditional	Uncertainty or variability in values and preferences
Very low	We have very little confidence in the effect estimate. The true effect is likely to be substantially different from the estimate of effect.	Conditional	Uncertainty about whether the intervention represents a wise use of resources

GRADE, The Grading of Recommendations Assessment, Development and Evaluation.

TABLE 6.4 Common Factors That Reduce or Increase the Quality of Evidence Using the USPSTF and GRADE Evaluation Systems

FACTORS THAT REDUCE EVIDENCE QUALITY	FACTORS THAT INCREASE EVIDENCE QUALITY
Limitations in study design or execution of methods with risk of bias	Large magnitude of effect
Lack of information on important health outcomes	All plausible sources of confounding would reduce the demonstrated effect or increase the effect if no effect was observed
Indirectness of evidence	Dose-response gradient
Imprecision or inconsistency of results across individual studies	Consistency of findings across multiple studies
Publication bias	Randomization employed or other valid methods used to adjust for measured and unmeasured confounding
Findings not generalizable to routine practice	Representative patient populations studied

GRADE, The Grading of Recommendations Assessment, Development and Evaluation; *USPSTF*, United States Preventive Services Task Force.

by the GRADE system from high evidence quality to moderate or even low evidence quality. In comparison, a single-center RCT with a large effect size or a dose-response gradient could be upgraded from moderate to high evidence quality. The updated USPSTF grading system uses similar criteria as GRADE for determining when evidence quality should be increased or decreased (Table 6.4). However, it is recognized that no single grading system is perfect, and surgeons are required to judge the quality and applicability of scientific evidence for themselves.

Evaluating Study Quality

Scientific evidence from surgical outcomes and health services research relies on two important inferences. The first inference is that the observed outcome is the result of some specific intervention and cannot be attributed to some alternative explanation. When conclusions are believable and this inference is deemed true, the study is considered to have internal validity. The second inference is that study results are relevant to scenarios outside the study where the surgeon seeks to implement the practice. In other words, do the study results apply to real-world clinical practice? The extent to which this is true is called *external validity* or *generalizability*. Whereas internal validity relies on how well the study is conducted and the results analyzed, external validity relies on how well the study plan reflects the clinical question that inspired it and how well the study's conclusions apply to scenarios outside the study. Poor external validity can also refer to the difference between an intervention's efficacy (i.e., how well it works when applied perfectly) and its effectiveness (i.e., whether it has the same effect when applied generally in an uncontrolled environment).

Internal Validity

Assessing the internal validity of a study requires an understanding of the potential influence of bias, confounding, and chance on the study results. Chance refers to the unpredictable randomness of events that might mislead researchers, whereas bias refers to systematic errors in how study subjects were selected or assessed. In comparison, confounding refers to differences in the comparison groups (other than the intended exposure) that lead to differences in outcomes.

Sources of bias. Multiple sources of bias might affect a surgical outcomes or health services research study.[36] Bias refers to a systematic problem with a clinical study that results in an inaccurate estimate of the differences in outcomes between comparison groups. Although several forms of bias arise in outcomes studies, two general types are most common: selection bias and measurement bias. The former results from errors in the choice of study subjects, whereas the latter results from errors in the way information about exposures or outcomes (or other pertinent data) is obtained.

Selection bias refers to any imperfection in the selection process that results in either the wrong types of subjects (i.e., people who are not typical of the target population) or a sample of subjects that for some reason unrelated to the intervention is more likely to have the outcome of interest. For example, paid volunteer subjects may be more motivated to comply with treatment regimens and report favorable results, resulting in an overestimate of the effect of an intervention. This would affect both internal validity (inference about the size of the effect) and external validity (generalizability to other populations). Selection bias is a frequent issue in observational studies of different treatment approaches (e.g., surgical vs. nonsurgical management of a condition) because selection of the approach by the clinician or patient eligibility is informed by variables that may not be measured. When assessing the validity of scientific evidence, surgeons must carefully consider the characteristics of the subjects selected for study.

Measurement bias refers to problems caused by the way information about outcomes or other pertinent data are obtained. For example, in a study of sexual function after surgery for open abdominal aortic aneurysm, subjects may report symptoms differently during an in-person interview than they would if mailed an anonymous survey. As another example, asking surgeons to assess surgical site infection outcomes in their own patients might result in erroneous reported rates as compared with surgical site infection rates reported by hospital epidemiologists. Retrospective studies, in particular, are prone to a variety of types of measurement bias. For example, “recall bias” may occur because of subjects’ selective memory of past events, and “ascertainment bias” may occur if the outcome is likely to influence how hard observers look for information about exposures. Sources of measurement bias may be subtler than selection bias and require careful attention to reported study methods. Efforts to control measurement bias include blinding (not telling the subject or assessor what intervention was performed) and prospective study design.

Confounding. Confounding refers to differences in outcomes that occur because of differences in the baseline risks of the comparison groups. These differences may occur because of selection bias that distributes risk factors known as *confounding variables* unevenly between comparison groups. Confounding variables influence both the outcome variable and exposure variable, causing a spurious association. For example, a comparison of mortality after open versus laparoscopic colectomy might be skewed because of the greater likelihood of open colectomy being performed as an emergency procedure in critically ill patients with perforation. In this example, the severity of the illness is a confounder in the observed association between mortality and surgical approach.

In evaluating the strength of evidence in a published study, readers must assess how well the researchers accounted for the potential effect of confounding. Confounding can be minimized in several ways, in both the design of the study and the analysis of the study’s results. In the design of a study, confounding is most effectively addressed with randomization. When subjects are randomized, potentially confounding variables (both recognized and unrecognized) are likely to be evenly distributed across comparison groups. Thus, whereas the baseline rate of outcomes in the entire cohort might be influenced by these factors, the differences across comparison groups are less likely to be affected.

When randomization is not practical, restriction or matching can be used to prevent confounding. Restriction refers to the tight control of study entry criteria, for example, only enrolling patients undergoing elective surgery and excluding emergent procedures. However, restrictive entry criteria can sometimes limit generalizability. In comparison, matching refers to using a comparison group of unexposed (control) subjects who are identical to the exposed (case) subjects across a set of characteristics (e.g., age, sex, residence) that have the potential to result in confounding.

In addition to minimizing confounding through good study design, confounding can also be addressed during the analytic phase of a study with statistical risk-adjustment techniques. The most common technique is multivariate regression analysis, including linear and logistic regression models. Logistic regression models are used when the outcome variable is binary, whereas linear regression is used when the outcome is continuous. Both of these approaches involve taking into account differences in the prevalence of recognized confounders across comparison groups. However, statistical risk adjustment has several important limitations. First, only recognized confounders can be addressed in the regression model. Second, every potential confounding variable added to a statistical model decreases the model’s statistical power and thereby increases the chance of resulting in a false-negative result (i.e., type II error). Third, regression model estimates are not very reliable when there are just a few outcome events. As a rule of thumb, logistic regression must have at least 10 outcome events for every variable adjusted in the model, whereas linear regression requires 10 to 15 outcomes per variable included in the model to prevent overfitting, the phenomenon where the model is fit too closely to the training set and therefore cannot be generalized.[37,38]

Other analytic techniques used to address confounding include stratification (subanalyses in which subjects with similar risk profiles are compared) and propensity score risk adjustment.[39] The latter technique addresses the problem created by unequal chances of receiving treatment caused by differences in health characteristics. In an observational study of the outcomes of a given treatment, a propensity score is a scalar summary of all observed confounders that predict the probability of receiving the treatment. Propensity scores are typically calculated using multivariate regression models and are used as the basis for stratified analysis or for matching cases and controls in observational studies.

Finally, another more complicated technique used to limit the effect of confounding is instrumental variable (IV) analysis. An IV approach involves studying the effect of a given exposure on outcomes by comparing groups with different levels of a third factor (i.e., the IV) that is highly correlated with the exposure but does not independently affect the outcome. For example, a study evaluating the effects of catheterization and revascularization on mortality after acute myocardial infarction would be prone to confounding related to differences in the baseline health characteristics of the populations receiving or not receiving these treatments. To limit this potential source of confounding, researchers studied the effect of receiving catheterization versus no catheterization (the exposure groups) on mortality after myocardial infarction (the outcome) by comparing groups of patients living at different distances from hospitals providing these services (the IV).[40] The researchers assumed that potentially confounding health characteristics would be distributed randomly geographically and that geographic distance would affect mortality only indirectly through its correlation with access to treatment. In this way, they used distance to “pseudo-randomize” their study population to different levels of treatment for acute myocardial infarction.

Hypothesis Testing

In clinical studies that compare outcomes between two or more treatment groups, the underlying assumption that no difference exists between groups is called the *null hypothesis*. Erroneous conclusions with regard to the null hypothesis can sometimes occur by chance alone. There are two types of chance-related errors: type I and type II. Type I errors (also called *alpha errors*) occur when researchers erroneously reject the null hypothesis, that is, infer that there is a difference in outcomes when there is no difference. Type II errors (also called *beta errors*) occur when researchers erroneously confirm the null hypothesis. In other words, the study concludes that there is no difference in outcomes between treatment groups when a difference truly exists.

Type I errors. Statistical testing is used to quantify the likelihood of a type I error. A "P value" indicates the probability that observed differences between groups might be the result of chance alone. In other words, the difference may not be based on the effect of the intervention being tested. The threshold for "statistical significance" is conventionally set at a P value of 0.05, signifying that the likelihood of the observed differences being the result of chance alone might occur 5 times out of 100 tests. Although a likelihood of 5% falls short of absolute certainty, this level of confidence is generally accepted as scientific proof and used throughout the scientific literature.

Type I errors can occur when the research question and analysis have not been specified a priori or when multiple statistical tests are performed in a study with several subgroups.[41] For example, with a P value set at 0.05, 1 out of every 20 comparisons will be expected by chance to be deemed statistically significant and be a false-positive finding. When more than 20 comparisons are necessary in a given study, a Bonferroni correction or Hochberg sequential procedure can be used to protect against a type I error.[42,43]

An alternative expression of statistical likelihood is the confidence interval. A confidence interval is a range of values that one can be certain contains the true mean of the population. Confidence intervals can also be defined as showing the range of the observed difference that would be expected if the same study were repeated an infinite number of times. For example, a 95% confidence interval would include the observed difference 95% of the times that the study was repeated. Factors affecting the width of the confidence interval include the size of the sample, the confidence level, and the variability in the sample. When all other factors are equal, a large sample size will tend to produce a better estimate of the population parameter.

Many statistical tests can be used to calculate P values and confidence intervals. The appropriate statistical test must be selected according to several factors. This includes (1) determining the number of observations in the comparison groups, (2) the number of groups being compared, (3) whether two or more groups are being compared with each other or one group is being compared with itself after some interval of time, (4) what kind of numerical data are being analyzed (e.g., continuous or categorical), (5) whether the sample is normally distributed (i.e., bell shaped) or has a skewed distribution, and (6) whether risk adjustment is required. Although most surgeons are unlikely to fully comprehend all of the nuances of more complex statistical analyses, the majority of surgical outcomes studies employ simple designs and statistical tests that are within reach of the nonstatistician to interpret.

Type II errors. Type II errors occur in studies where the null hypothesis is falsely accepted. This often arises when the sample size is simply insufficient to detect small but clinically important differences in outcomes. When a study's sample size is too small to detect differences in outcomes between comparison groups, it is said to lack sufficient statistical power. But once a study is complete, no amount of analysis can correct for insufficient statistical power. Before starting a prospective study, researchers should perform a *power calculation,* which involves determining the minimum size of a meaningful difference in outcomes and then calculating the number of observations required to show that difference statistically.[44] Surgeons should be particularly cautious when evaluating studies with null findings, particularly when no power calculation is explicitly reported. Moreover, a post hoc power analysis can also be helpful with interpreting study results from retrospective studies when no statistically significant effects are found.[43] An evidence-based surgeon is wise to remember the adage, "no evidence for effect is not necessarily evidence of no effect." Further, there are specific methods for performing noninferiority studies, which differ from a study that is designed to identify a difference and fails to do so.

INTERPRETING AND APPLYING EVIDENCE TO SURGICAL PRACTICE

Once one is convinced that the observed outcome from a clinical study is the result of the exposure or intervention and cannot be attributed to some alternative explanation (i.e., it is internally valid), then the next challenge to the surgeon is judging the study's external validity. In other words, you must determine whether the findings are applicable to the specific clinical scenario you are facing. Interpreting and applying evidence to surgical practice require a careful assessment of each study's external validity.

The assessment of external validity requires attention to core components of a clinical study, including the patient population, the intervention, and the outcomes that were measured. Even evidence derived from a well-designed, prospective RCT may not be valid if the population that was studied is different from the patient groups for which a surgeon is making clinical decisions. For example, consider the well-publicized multicenter randomized clinical trial that was conducted in the US Department of Veteran Affairs (VA) to compare laparoscopic versus open inguinal hernia repair.[45] This study randomized military veterans who were, on average, older than the nonveteran general population that undergoes hernia repair and concluded that outcomes of open repair are superior to those of laparoscopic repair. But older subjects are more prone to the risks of general anesthesia needed for laparoscopic hernia repair, whereas simple open hernia repair can often be performed using local or monitored anesthesia care. In this respect, a surgeon might consider the evidence provided by the RCT applicable to older patients but reserve judgment on the use of laparoscopy to repair hernias in younger, healthier patients.

As noted earlier, subject selection bias can adversely affect the external validity or generalizability of a study's results. Another example of the potential effect of selection bias on generalizability comes from the Asymptomatic Carotid Atherosclerosis Study (ACAS) trial.[46] In this large, prospective randomized trial, enrolled subjects were substantially younger and healthier than the average patient who undergoes carotid endarterectomy (CEA). As a result, the observed perioperative mortality rate in the trial was considerably lower than that observed in the general population or even in the very hospitals where the trial was conducted. Although the results of the ACAS trial significantly changed practice, one could argue that the evidence provided should be applied only to younger patients with asymptomatic carotid stenosis.

The external validity of a clinical study can also be dependent on the surgeon who intends to apply the evidence, along with their experience and expected outcomes. In the VA hernia trial, surgeons had variable experience with the laparoscopic approach, and the trial reported twofold differences in hernia recurrences between surgeons who had done more than 250 cases and surgeons who had less case experience.[45] Surgeons deciding whether the trial evidence supports the use of laparoscopic repair would need to examine their own experience before determining the generalizability of this study to their practices. In the ACAS trial, the surgeon selection process mandated that expected CEA outcomes for any given surgeon must carry a combined stroke plus mortality rate of ≤3.0% for asymptomatic patients.[46] As such, surgeons deciding to perform CEA for asymptomatic carotid stenosis based on the trial evidence must also be able to perform this operation with outcomes that are at least as good.

The type of outcome measured can also affect the generalizability of clinical studies. Outcomes chosen for clinical studies may be those that are most convenient or most easily quantified and may not be the outcomes of greatest interest to patients. In the VA hernia trial, several outcomes were studied, including operative complications, hernia recurrence, pain, and length of convalescence. Some of the outcome differences favored open repair, whereas some favored laparoscopic repair. The interpretation of the trial evidence for one type of repair versus the other involves implicit value judgments regarding which outcomes are most important and relevant to patients. This issue was also illustrated by findings from the Carotid Revascularization Endarterectomy versus Stenting Trial (CREST), in which patients with carotid stenosis were randomized to either CEA or carotid artery stenting.[47] Although the study composite end point (stroke, death, or myocardial infarction) did not differ between carotid artery stenting and CEA, there were still significant differences in individual outcome measures. Patients who underwent carotid artery stenting experienced higher rates of stroke than CEA, whereas patients who underwent CEA were found to have a higher risk of myocardial infarction. As such, surgeons applying evidence from CREST to preoperative decisions about method for carotid revascularization must weigh the relative risk of having a postoperative stroke versus a myocardial infarction outcome for an individual patient. This can be incorporated into a shared decision-making process that considers the goals and preferences of the patient.

CONCLUSION

The practice of evidence-based surgery relies on the judicious and systematic application of research evidence to everyday surgical decision-making. With an ever-expanding body of published surgical outcomes and health services research studies, knowing how to interpret the literature becomes increasingly important. Surgeons must be able to appraise the strength of scientific evidence and evaluate the quality of research studies before making decisions whether to apply the evidence to their own clinical practice. Consistently applying evidence-based medicine practices will help maintain high-value surgical care. Lastly, partnering with nonsurgeon experts in clinical trial design and data analysis and interpretation is critical for the development and dissemination of high-quality surgical science to improve delivery of surgical care in the future.

BACKGROUND

It is well known that low-quality care results in harm to individual patients and has a significant economic burden on patients, hospitals, payers, and the overall healthcare system. More than two decades ago, the Institute of Medicine (IOM), now the National Academy of Medicine, Committee on Quality of Health Care published *To Err Is Human,* describing widespread patient safety issues in the United States and concluding that considerable variations exist in patient care across regions, hospitals, and individual practitioners. The IOM highlighted six key domains of quality patient care: safety, timely, effective, efficient, equitable, and patient centered to provide a structure for subsequent improvement efforts.[1,2]

The IOM concerns were particularly relevant in surgery, in which variation in outcomes is well documented and improvement efforts can be quite effective.[3] For an historical example, consider the publicly reported variation in perioperative mortality after coronary artery bypass surgery (0%–15%) across hospitals and systems in New York State.[3] Quality improvement (QI) efforts were developed and instituted that resulted in a mortality reduction by over 40%.[3] In addition to other factors, this experience motivated the expansion of surgical QI programs. Although significant improvement has been achieved, continued variation in the quality of care and the constantly changing healthcare landscape are reminders of the need for continuous QI efforts within the field of surgery.

QI methodology comes in a variety of different forms, which all rely on data capture, measurement, and reporting. Many programs and methods have been proposed, all with unique strengths and weaknesses. This chapter will discuss many of these and provide a foundation of knowledge regarding the measurement of quality and the challenges associated with QI. We first will discuss specific ways to measure and report quality, then we will go into a discussion of various data collection methods, and we will finish with mechanisms and programs in place for surgical QI. Challenges and future directions of surgical quality will be discussed throughout the chapter.

SURGICAL QUALITY MEASUREMENT

Surgical quality can be captured in many ways. Conventionally, this has been based on Donabedian's conceptual framework: structure, process, and outcome (Table 7.1).[4–6] Each of these domains carries unique strengths and weaknesses and is the foundation of QI work (Fig. 7.1). True quality relies on facets of each domain. Although surgical quality relies primarily on clinical outcomes assessment, such as morbidity and mortality, more recently, a call to consider other elements of quality is underway.[7,8] Examples include cost-effectiveness or value of care, patient-reported measures, and health equity.[9]

Structure

Structural components of quality are usually blunt measures determined by the setting in which care is delivered. Examples of structural components include hospital volume, provider-specific case volumes, availability of subspecialty services, and nurse-to-patient ratio. Measuring structural components is generally easy and readily available, mainly because they carry universal definitions and are a quantitative value. Limitations lie within the specific mechanistic relationship of these structural components to actual healthcare quality.

One simple example is the volume-outcome relationship. This metric is frequently used in quality assessment; however, the

TABLE 7.1 **Donabedian's Framework Components Including Definitions, Examples, Pros, and Cons**

	STRUCTURE	PROCESS	OUTCOME
Definition	Setting and components of where the care is being delivered	Series of steps taken to deliver clinical care	End points in care
Examples	Hospital volume, providers available, nurse-to-patient ratio	Perioperative antibiotic use, adjuvant therapy, deep venous thrombosis prophylaxis	Morbidity, mortality, recurrence
Pros	Universal definitions, quantitative, easy to study and collect	Minimal data collection burden, linkage to some outcomes	Easy to assess, interpret, and compare
Cons	Difficulty drawing relationship between measure and quality of care provided to patient	Difficulty defining patient cohort, unclear relationships between quality and process measures	Not always best surrogate, rare events, increasingly susceptible to bias

FIGURE 7.1 Conceptual model of quality improvement *(QI)* collaborative. (From Wandling MW, Minami CA, Johnson JK, et al. Development of a conceptual model for surgical quality improvement collaboratives: facilitating the implementation and evaluation of collaborative quality improvement. *JAMA Surg.* 2016;151[12]:1181-1183.)

actual mechanisms that account for the association between volume and outcome are often heterogenous depending on the hospital context and, for the most part, have not been elucidated.[10] In an attempt to protect the public against unqualified providers, standard minimum volume thresholds for specific operations have been put in place by national societies and accreditation boards.[8,11,12] These efforts have been met with mixed reactions because of the imperfect relationship between volume and outcomes. For example, there are examples of low-volume surgeons and/or hospitals that provide exceptional quality of care because of access to mentors and subspecialty providers or services. As such, volume alone, a structural component of quality, is not as obvious as it may seem. It is more important to further evaluate underlying institutional factors and mechanisms that lead to differences in outcomes, not only on an individual structural component.[13]

Process

Process measures refer to the actual clinical care provided to patients. Examples include receipt of adjuvant therapy in colon cancer and perioperative antibiotic use (Surgical Care Improvement Project [SCIP]). Processes of care are an easier way to evaluate individual hospital quality and variation because process measures are not limited by event rates or the need for complex risk adjustment.[14,15] Other benefits include a minimal burden to collect data and a clear linkage to some outcomes (i.e., patients receiving venous thromboembolism prophylaxis). However, many challenges exist when using process measures. One particularly challenging issue includes appropriately defining the numerator (e.g., delivery of adjuvant chemotherapy for colon cancer) and denominator (e.g., patients eligible for adjuvant chemotherapy).[16] Another challenge includes a clear connection between the process measure and specific outcome. For example, adherence to individual SCIP measures was not associated with improved quality outcomes, but the bundle did affect outcomes.[17,18] Similar examples exist with surgical site infection (SSI) prevention strategies before colorectal surgery with implementation of SSI reduction bundles, as seen with the Illiana State Quality Improvement Collaborative.[19] In summary, processes of care are easier to evaluate and measure, but defining what is truly the right cohort at the right time is challenging, and there may not always be a clear one-to-one relationship with the outcome of interest.

Outcomes

Another mechanism to evaluate quality is to measure outcomes. In surgical quality assessment, outcomes usually refer to morbidity or mortality. These measures are used across consumers, providers, purchasers, and other key stakeholders. Sometimes they can be easily accessed and interpreted, which has become increasingly valuable to patients when making decisions on where to seek treatment.[20,21] Moreover, because outcomes are considered the "bottom line" of quality by some, providers are able to unambiguously benchmark their performance to peers and evaluate the effects of QI efforts.

Outcome measures also contain several limitations. Although they are the end points of care, they are not always meaningful surrogates of quality. For example, mortality is a primary focus of outcome data. Mortality has a low collection burden and cost, has a standardized definition, and is accessible from administrative sources. Yet mortality is a rare event, often not the result of an easily identified preventable event and not actionable or generalizable to other scenarios. Focusing excessive amounts of resources on mortality reduction in the limited-resource environment at most hospitals may not result in measurable improvement in care. Outcome measures are also susceptible to biases, limiting their use in QI. For example, certain complications may be susceptible to surveillance bias, where more vigilant hospitals and providers look harder for complications, potentially revealing many subclinical events. This has been described for venous thromboembolism complications.[22,23] Another main challenge of using outcome measures is developing valid, reliable, and accurate risk adjustment models. These models have been increasingly used in research and publication to improve the classification of "quality" of a particular institution to "level the playing field." Defining and standardizing variables across hospitals or providers are seemingly basic concepts but are frequently labor intensive and intellectually challenging tasks.

Patient-reported outcomes (PROs) represent another type of outcome measure that is now a reporting requirement for certain procedures.[24–27] PROs represent the important notion that quality of care should include the individual patient's perspective.[4] PROs, such as quality of life, functional outcome, pain control, sexual function, and depression, are increasingly used as measures of quality.[28] Although a surgeon's primary focus used to lie solely on outcome measures such as margins, lymph node dissection, morbidity/mortality, and other factors, the focus has shifted toward these other patient-centered and patient-reported measures.

Nevertheless, PROs have significant limitations, especially in surgery.[29] Using PROs is not always relevant to certain procedures and may not be comparable across groups or hospitals. Measurement is especially difficult because it requires patient participation, and it can be difficult to obtain complete data at specific time points for accurate measurement and comparisons.[30,31] PROs may have more use at the individual level—where providers can enhance shared decision-making discussions and subsequently improve patient outcomes.[30,32]

There are both facilitators and barriers to implementation of PROs reporting within healthcare settings. Studies have shown that patients have concerns about questionnaire length and privacy of health data.[33] There is concern for clinicians on where these data go, implementation into the electronic health record (EHR), and appropriate alerts to the correct provider. PROs used for postoperative recovery monitoring should consider not only the technical and implementation needs but also the utility of PROs to predict clinical outcomes.[34,35]

Other Measures of Quality: Accessible, Timely, Appropriate, Value, Equity

Surgical quality should also be measured with accessibility, timeliness, and appropriateness of care.[36,37] First, care needs to be accessible. This may be evaluated based on location and availability for each individual patient. A hospital may have "good" outcomes; however, if excessive wait times exist and/or patients do not receive the most appropriate care (i.e., the right care at the right time), it can be argued that surgical quality is deficient.[4] Comparative performance assessments should also include the value, or quality per unit cost, of care.[4,35] Vizient (formerly the University HealthSystem Consortium) and Centers for Medicare and Medicaid Services (CMS) measures have incorporated costs into the reported metrics used for hospital comparisons. As with any measure, there are many limitations to these parameters, yet audit and feedback of risk-adjusted cost data will allow hospitals to evaluate the value of their care compared with peer institutions and may not only be an effective cost containment strategy but also allow the needed transparency for patients.[9]

DATA SOURCES AND COLLECTION

Quality measures are limited by the data on which they were derived. This makes the data source selection and collection process a fundamental aspect within surgical quality work. Data sources are described in two major categories: clinical and administrative.[4] As with the quality measures discussed, each source of data contains advantages and disadvantages for use. Combination sources, created by data merges, can provide a robust set of information to study quality and enact improvement.

Clinical

Clinical data are derived from unique clinical encounters of subsets of patients. They are usually collected by trained clinicians, registrars, or providers familiar with individualized patient care. These data, once collected, are primarily used for research or quality metrics (not for billing purposes). Clinical data can be designed for QI measurement because they can be collected with sampling approaches and specific data definitions for QI. One of the best examples is the American College of Surgeons National Surgical Quality Improvement Program (ACS NSQIP). ACS NSQIP data are required to be collected by clinically oriented abstractors who use standardized definitions. This results in proven interrater reliability and high-quality data collection.[4] It is for this reason that clinical data tend to be more reliable and accurate than administrative data.

There are important disadvantages with clinical data. A considerable number of resources and time are required to collect data. For programs that are a part of the ACS NSQIP program, each must employ a full-time data collector and pay significant fees to participate. In addition, collecting accurate and reliable data takes time. Another pitfall of clinical data is the challenge of capturing data between hospital systems and longitudinally over time. Although most clinical definitions remain the same over time, some aspects of care, such as International Classification of Diseases (ICD) codes or cancer staging, have progressively adapted and changed. An example is the change in breast cancer staging with developments in tumor markers/receptor status, genetics, and tumor grade.[38] Because of the high impact of resources required for clinical data, clinical data are often only able to sample a subset of patients rather than large populations.

Administrative

The other category of data collected comes from administrative sources. Administrative data are collected for alternative purposes such as billing for healthcare services. The data collected tend to have increased complexity and can pose challenges to use and manipulate compared with most clinical data. Only information that is relevant to billing will be collected, which creates a large gap regarding other metrics for quality. In comparison to clinical data, administrative data both overreport and underreport complications.[39]

Administrative data also have several strengths. Administrative data impose significantly less cost and collection burden on an individual hospital. The data collected are already a part of the system and its billing processes. With administrative data, it is also easier to study patients longitudinally over time. These two strengths give administrative data the ability to assess an increased and more representative sample. Administrative data also help to capture healthcare costs, which can provide an important aspect to QI measurement.

Data from the EHR may fall under either category, clinical or administrative. The data are derived from clinical encounters and include documentation by clinicians; however, because many EHRs are used for billing purposes, some of the data may be structured more like administrative datasets. As such, it is critical to understand the actual data acquisition process employed when evaluating the validity, reliability, and accuracy of data obtained from the EHR.

Depending on the surgical quality measurement required, clinical and administrative data sources are used for various reasons. An important look at the strengths and weaknesses of both is crucial before use of a particular set of data with QI.

CHALLENGES IN SURGICAL QUALITY MEASUREMENT AND REPORTING

Risk Adjustment

Surgical outcome measurement relies on accurate risk adjustment. Risk adjustment, in the context of hospital quality measurement, refers to using statistical methods to decrease variability in case mix between hospitals so they can accurately be compared with one another. The types of patients treated at individual hospitals and systems may vary substantially. Patients can have a wide range of comorbidities, distinct social determinants of health, and differences in surgical complexity. If one hospital cares for and performs operations on patients with extensive comorbidities, they may appear to have worse quality and outcomes than another hospital with different patient characteristics. An appropriate risk adjustment methodology may be able to adjust for differences in patient characteristics if the characteristics are observable. Unmeasured confounding is common because many unobserved factors influence healthcare outcomes. For example, the extent of complexity of the surgical procedure may not be able to be systematically quantified and would reflect an unmeasurable element of risk.

Clinical data warehouses, such as the ACS NSQIP, store extensive data on demographics, comorbidities, and preoperative laboratory values to aid in risk adjustment across hospitals.[40] A challenge that has made significant improvements but still requires more work is surgical complexity adjustment. Hospital systems and surgeons have raised concerns about including surgical complexity in risk adjustment models, which has been examined in a number of previous studies.[40–42] These studies highlighted that a primary procedure code such as hepatectomy or partial colectomy does not adequately describe a procedure's level of difficulty. This is further exacerbated if a secondary procedure is performed synchronously. This can be seen in many complex cancer surgeries in which the level of difficulty is not appropriately captured by the primary procedure code alone. Treating benign disease is intuitively different than advanced cancer resections (e.g., colectomy with resection of bladder, lymph node dissection, liver resection). Alternatively, increased complexity can be seen in a sigmoid colectomy for complicated diverticulitis in comparison to a straightforward hemicolectomy for colon cancer. ACS NSQIP includes case complexity in its national benchmarking of hospitals, but further work is still required to evaluate the complexity of the specific operations.

It is important to note that not every aspect of risk and complexity are required to accurately measure risk-adjusted outcomes. Comparisons between hospitals do require some risk adjustment, but it is likely less than our intuition would suggest.[4] Hospital quality rankings have shown to be near identical with risk adjustment models for many procedures in ACS NSQIP. It is important to note that adjustment for age, American Society of Anesthesiologists (ASA) class, functional status, extent of surgery, and the indication for surgery means that most of the risk adjustment has been captured.[4] Therefore, we are likely leveling the playing field with the variables already captured.

Reliability

Reliability can be described as the amount of consistency a particular measure or assessment has with repeated observations. If data and method have a 100% reliability, a real difference in performance can be attributed to the variation in the data. Conversely, a reliability of 0% indicates that all differences noted in the data are merely the result of noise. Because of the high stakes of quality measurement, reliability is especially important in development and evaluation of quality. Consumers' choice from public reporting and insurance companies determining pay reimbursement are important examples of stakeholders that depend on reliable quality data. Reliability is especially essential when assigning poor performance.

TABLE 7.2 **Estimated US and ACS NSQIP Hospitals Meeting Annual Colectomy Caseloads by Reliability**

RELIABILITY	CASES[a]	AMERICAN COLLEGE OF SURGEONS NATIONAL SURGICAL QUALITY IMPROVEMENT PROGRAM HOSPITAL (%)[b]	US HOSPITALS (%)[c]	PROPORTION OF ALL CASES IN UNITED STATES (%)[c]
0.2	20	92.9	66.6	96.5
0.3	36	82.3	53.4	91.6
0.4	56	68.6	41.8	84.4
0.5	80	56.9	31.6	75.2
0.6	114	39.6	22.1	62.8
0.7	166	14.9	12.5	44.5

[b] Based on number of sampled cases submitted to the American College National Surgical Quality Improvement Program from each hospital.
[c] Estimated from 2008 nationwide in-patient sample data.
From Merkow RP, Hall BL, Cohen ME, Wang X, Adams JL, Chow WB, et al. Validity and feasibility of the American College of Surgeons colectomy composite outcome quality measure. *Ann Surg*. 2013;257(3):483-489.

There is no "acceptable" level of reliability that is clear for all purposes. Various proposals of 0.4 are considered acceptable, but others can range to a level of 0.7. Because of the challenges with this issue, the National Quality Forum recommends thresholds vary under different circumstances.[4] Reliability must be balanced with practicality. One example to demonstrate this difference looks at the ACS composite quality measure. Only 56 cases per hospital must be collected for a moderate reliability of 0.4, compared with the 166 cases per hospital, a mere 13% of US hospitals, if using a very high reliability of 0.7 (Table 7.2).[43] Striking a balance between rigor and burden, the ACS proposed a reliability of at least 0.4, or "moderate" reliability, for this particular measure.[4,43] Furthermore, internal hospital QI reliability is likely less important because any information regarding that hospital's or system's performance can direct internal quality initiatives. Reliability must be used in surgical quality measurement and provided to hospitals for comparative data regarding hospital surgical quality.[4]

Attribution

Attribution is an important aspect to consider when measuring and reporting quality. Attribution is defined as explicitly assigning performance (either good or bad) to an element of care or an individual. This becomes increasingly relevant as it relates to attribution of outcomes to individuals. Individual physician patient-experience scores have become widespread on the web. This has raised concerns regarding the potential for inappropriate attribution based on sex, age, or training experience.[44] High-quality healthcare is a multidisciplinary effort from a wide range of individuals and teams. For surgical care, this includes but is not limited to surgeons, residents, hospitalists, nurses, respiratory therapists, physical/occupational therapists, scrub technicians, office assistants, medical assistants, receptionists, and social workers. It is also important to note that an individual patient's characteristics outside of their physical health may also affect their outcomes such as education level, religious beliefs, and access to resources. Imagine a patient review of an office visit where there was a line to check in, a wait for vital sign assessment, and a delay in rooming. Perhaps this patient saw the surgeon the moment they got into the examination room, yet, from their perspective, they were already 30 minutes late. This might cause them to rate the experience poorly with respect to timeliness. The rating would be assigned to the surgeon, and yet, they were on time and, in fact, were waiting for the patient to get into the room. Can we therefore attribute a worse-than-expected outcome solely to the surgeon in question? Thoughtful evaluation of individual data sources and/or comparison groups should be explored before any attribution is made solely to a single individual.

Defining and Reporting Results

The final consideration we will describe lies within defining and reporting results. An important aspect of this is benchmarking to define outlier hospitals to target for QI. The method behind defining a hospital as an outlier should revolve around the primary quality measure and improvement process/action.[45] There are external and internal interests when assessing hospital performance. External interests include satisfying oversight agencies to meet mandatory quality requirements, public reporting activities, or reimbursement incentives. Internally, hospitals need to be able to confidentially identify areas potentially in need of improvement.[4] It is incredibly important to distinguish between internal and external methods of reporting hospital performance because defining an outlier can have significant consequences. Defining an outlier externally requires strict and transparent criteria. This is different from an internal method because identifying outliers can allow for potential improvement in patient care without having external pressure and consequence. For example, ACS NSQIP uses a strict definition of outlier status based on statistical significance ($P < 0.05$) and reliability adjustment for its National Quality Forum and public reporting models.[4] In contrast, for internal purposes, ACS NSQIP relaxes the criteria used to designate internal outliers.[4]

Another important aspect of defining and reporting quality involves hospitals reaching minimum standards or becoming compliant but not actually improving quality. Once an oversight agency defines quality measures, hospitals enact change to improve their compliance with those particular measures but may also sacrifice resources on other measures that are more internally relevant to the institution. This is why it becomes increasingly important to measure the downstream effects of quality measures/initiatives and minimize the burden of excessive data reporting.[11] This will aid in defining true quality and reporting of data and will improve patient care, which is, of course, the fundamental goal of measurement and reporting.

Lastly, an important consideration involves the fact that the actual reporting of surgical quality has proved challenging and often varies by the audience (e.g., clinicians, administrators, patients, caregivers). Some rating schemas use a star system for poor (*), average (**), and good (***) performance, others use numbers (e.g., rates), and others use simple phrases such as “worse than expected,” “better than expected,” or “as expected.”[4] There is not a single right or wrong way to report performance, but it is important to communicate information simply and effectively to your audience.[4]

MECHANISMS FOR IMPROVING SURGICAL QUALITY

There are three ways to use data to improve surgical quality. First, report hospital performance data to the hospitals. This proven approach relies on hospitals found to be poor performers to enact local QI initiatives within their institution to improve care.[46] Another strategy is to publicly report data on hospital quality. This mechanism is aimed toward consumers to engage and inform them about hospital and physician quality. This gives consumers the opportunity to make educated decisions on where to seek high-quality care. In theory, this approach should also push hospitals to enact QI initiatives to maintain market share. A final mechanism involves using data to drive reimbursement (e.g., pay-for-performance). This involves measuring a provider’s performance and then linking that quality of care to a financial incentive or penalty, typically a percentage holdback. Providers are therefore able to link performance and quality with payment. This can be done using an absolute cutoff value of quality, in which every hospital can succeed, or using comparative data, in which some excel and others fail to meet performance expectations. Although stakeholders may have a wide range of motivations and interests, they share one fundamental principle: a reliance on high-quality data and accurate measurement methodologies.[4]

PROGRAMS TO MEASURE AND REPORT SURGICAL QUALITY

QI has been reported, tracked, and completed by many different programs and initiatives (Table 7.3).[4] Several surgical quality programs such as ACS NSQIP use clinical data.[47–49] ACS NSQIP was originally developed within the United States Department of Veterans Affairs (VA) system after extreme criticism regarding the quality of care within VA medical centers. From 1991 to 2006, the VA hospitals had a greater than 40% decrease in postoperative mortality and morbidity.[50] After the success within the VA medical centers, the program was expanded by the ACS and tested within non-VA hospitals. ACS NSQIP “became the first nationally validated, risk-adjusted, outcomes-based program to measure and improve quality of surgical care across the surgical specialties in the private sector.”[50] As of 2023, over 700 hospitals currently use the program. ACS NSQIP relies on the collection of high-quality clinical data by independent trained data abstractors using standardized definitions, accurate and reliable risk adjustment, and timely performance feedback to

TABLE 7.3 Examples of QI Organizations, QI Report Cards, and QI Collaboratives That Measure Quality

participating hospitals.[4] ACS NSQIP continues to expand, both with the number of hospitals and its initiatives and partnerships. Some of the partner organizations include the National Quality Forum, the Centers for Disease Control and Prevention, and the Centers for Medicare & Medicaid Services.[4] ACS NSQIP now measures procedure-specific variables and outcomes to permit appropriate risk adjustment and target quality of surgical care for individual operations (e.g., pancreatic leak after pancreatectomy). Occasionally, new initiatives pose unique challenges such as reduced reliability in the setting of greater granularity.

Many other programs and collaboratives collect and measure surgical quality using clinical data. These include but are not limited to programs such as the Society of Thoracic Surgeons (STS), New York State Adult Cardiac Surgery program, and National Cancer Database (NCDB) and collaboratives such as the Michigan Surgical Quality Collaborative (MSQC), Surgical Clinical Outcomes Assessment Program (SCOAP) from Washington State, and the Illiana Surgical Quality Improvement Collaborative (ISQIC).[4] Each of these examples also has its unique strengths and weaknesses. The STS and the New York State Adult Cardiac Surgery program focus on cardiac and thoracic surgery and therefore collect risk-adjustment variables and outcomes specific to those operations.[4] The NCDB is a hospital-based clinical cancer registry established in 1989 that collects data from more than 1500 hospitals in the United States, capturing more than 70% of all newly diagnosed cancers.[51] Although this database is limited at times because of missing data, it has been widely used for research and QI in cancer care. These data sources are also limited by participation and data submission. Regional collaboratives, such as MSQC, ISQIC, and SCOAP, offer hospital-specific geographic areas the opportunity to collaborate on QI initiatives. Not all hospitals are included, making them less generalizable to the overall population. All these data sources have been used for QI initiatives.

Many organizations exist that use administrative data to assess performance. These include Vizient (formerly the University HealthSystem Consortium), Health Grades, the Leapfrog Group, Consumer Reports, and *U.S. News & World Report*.[4] Most of these programs focus on Medicare data. This allows the datasets to evaluate a larger number of hospitals, operations, and outcomes among patients enrolled in Medicare programs. These datasets also include costs of care and patient-experience survey data, giving rise to the critical PROs. Because of the breadth of measurement and reason for collection, many of these data sources contain measurements not relevant to surgery. Despite this limitation, these administrative data sources provide unique data regarding hospital quality.

Surgery-Specific Quality Initiatives

Unique surgical initiatives have been developed over the past few decades to improve and address specific complications and aspects of surgical care. These include but are not limited to SSI reduction programs and enhanced recovery after surgery (ERAS) programs (ERPs).

SSIs are described as the most frequent cause for readmissions after colectomy procedures.[52] These SSIs are an actionable metric for QI because SSIs are not correlated to overall rates of SSI or overall readmission rates.[53] Improving readmission rates because of SSI would improve patient satisfaction and reduce overall costs, thereby improving quality of healthcare delivered. Reducing SSIs has been shown via various interventions—“prophylactic antibiotics, bowel preparation, smoking cessation, glycemic control, normothermia, and intraoperative contamination mitigation.”[54] ISQIC implemented an SSI reduction bundle and observed a 30% decline in SSIs.[55] Adherence to these bundles varies by hospitals, so SSI reduction continues to be a major target for QI.[54]

ERPs have been discussed for a little over a decade now in the literature. This was originally seen most aggressively with colorectal surgery because of the relatively high postoperative morbidity and potential for improvement. A recent review was published that evaluated elective colectomies from 2013 to 2018 caused by the rapid national expansion of implementation of these quality measures. They found significant reduction in overall morbidity, SSI, readmission, and length of stay.[56] Even in low-resource settings, ERPs were feasible, safe, and effective in improving quality after both open and minimally invasive colorectal cancer surgery.[57] Thomas et al. also demonstrated that even with incomplete adherence to the pathway, incremental benefit is still observed. ERPs or ERAS have shown significant improvement in a multitude of different settings, including pediatric surgery, which is notoriously a difficult area to implement change.[58,59] As more is learned about the most effective ERP/ERAS implementation across all disciplines within surgical subspecialities, this will become the new normal for perioperative care.

Collaboratives as a Mechanism to Improve Quality

Many hospitals have joined quality improvement collaboratives (QICs) to work on common goals across a geographic region or specialty (see Fig. 7.1).[60,61] QICs have proven to reduce complications and decrease costs.[60,62,63] For example, for the first 3 years after its development, “the Illinois Surgical Quality Improvement Collaborative (ISQIC) focused on (1) how the collaborative was formed and funded, (2) the 21 strategies implemented to support QI, (3) statewide initiatives undertaken to date, (4) collaborative sustainment, and (5) how the collaborative acts as a platform for innovative QI research.”[19,61] They created a model where hospitals within Illinois had a local QI team that consisted of a surgeon champion, a surgical clinical reviewer, and a QI leader (administrator or operational leader). Two of the initial QI collaborations involved postoperative venous thromboembolism prophylaxis and SSI reduction. Each produced significant results.[54,55,64] Participation in ISQIC and implementation of QI initiatives resulted in a significantly greater improvement in death and serious morbidity compared with national rates.[19,60]

QUALITY IMPROVEMENT TEAMS

When establishing and starting a QI project or collaborative, it is essential to consider what team of people is required for success. When evaluating any problem, big or small, a significant number of stakeholders are at play. Consider decreasing line infections in the neonatal intensive care unit (NICU). There is the patient and family, the bedside nurse, the charge nurse, respiratory therapist and other ancillary staff, students, residents, fellows, neonatologists, surgeons, other subspecialists, various line and dressing companies, and national institutions with policies and procedures regarding line care. These stakeholders are all necessary to consider when establishing a QI team. Swanson et al. suggests creating a stakeholder map where individual stakeholders are grouped. Taking data from that map can help establish who needs to be involved to represent that particular group of stakeholders to form a successful project.[65] It is also important to include stakeholders who may initially carry some resistance to the change/adaptation. Including their input up front can potentially decrease later problems and delays. Teams may also change as time goes on; new stakeholders may be identified. It is important to consider team changes if these aspects are discovered.

Establishing individual roles within the team is also important. Roles include project champion, technical expert, clinical leader, project sponsor, and process owner.[65] Each role carries unique responsibilities in terms of the success of the team. When placing team members into roles, it is crucial to consider the influence and power certain stakeholders carry that can affect team dynamics. The team champion is truly the leader of the group. This person should be invested in the project and its potential impact. They will manage all day-to-day activities related to the project. The technical expert brings to the table their perspective on the problem and has knowledge on basic QI methodology. The clinical leader is the stakeholder who can actually enact the proposed changes and will carry the knowledge on if this will affect aspects of care outside of the project or designated area. The project sponsor is the stakeholder who is responsible for knowing from whom, where, and how to obtain necessary resources for the project, monetary and otherwise. Lastly, the process owner is the stakeholder who is responsible for establishing a sustainable measure to continue the QI process after completion of the project.[65]

CURRENT METHODS OF QUALITY IMPROVEMENT

QI methods are in no short supply. Many are variations of each other, built to accommodate a particular project or institution. A few are highlighted next (Table 7.4).[66–71]

Plan-Do-Study-Act Cycles

The Plan-Do-Study-Act (PDSA) framework for research and quality was established in the 1930s and has been a major outline for projects and improvement since that time.[72] PDSA cycles provide structure for change within a system, either by themselves or as part of another larger QI approach.[73] "In the 'plan' stage a change aimed at improvement is identified, the 'do' stage sees this change tested, the 'study' stage examines the success of the change and the 'act' stage identifies adaptations and next steps to inform a new cycle."[73] These stages were based on the experimental method to formulate an iterative approach to implement interventions.[74] PDSA improvement research is primarily outcomes based. Critics have stated that PDSA cycles do not contain enough rigor and may not be applicable on a larger scale. In fact, Taylor et al. discussed overall lack of adherence to key principles of this method—leading to a wide variability in effective outcomes with this model. They call for greater rigor on the application and reporting of this method to ensure reliability of implementation of QI.

Balanced Scorecard

Another QI methodology is named the Balanced Scorecard. Kaplan developed this strategic management tool that provides "sets of operational measures having to do with customer satisfaction, internal processes, and the organization's ability to learn and improve—the activities that drive future financial performance."[75] The Children's Health Airway Management Program (CHAMP) used this methodology in their QI initiative to improve tracheostomy outcomes.[70] Their scorecard used "4 perspectives: clinical excellence, operational excellence, exceptional experience, and financial strength."[70] They established a multidisciplinary team that improved quality outcomes using this method.

Define, Measure, Analyze, Improve, Control

DMAIC is the methodology employed by Lean and Six Sigma. Lean was established by Toyota to eliminate waste and thereby improve efficiency of a process.[76] Combining Lean and Six Sigma and using the DMAIC method for QI allows for a reduction in process variation.[77] The steps of DMAIC are define, measure, analyze, improve, and control. Defining a project's objective(s) is likely one of the most influential steps. All stakeholders must develop and agree to the specific aims of the project. Within the define phase, one must also identify how success of the project will be measured.[78] In the next step, measure, key data indicators are identified. Within this step, initial data collection may be required for baseline characteristics. It is crucial during this step that the project leader identifies the accuracy and reliability of the data to avoid false justifications of the project. Next, analysis of the data ensues. This step involves identification of "causes of errors, deviation, delays, waste, or other etiologies of defects in the process."[77] Many different tools can be used for analysis such as Pareto diagrams or a 5-whys analysis. Once thorough analysis of the problem to find a root cause has been conducted, the project

TABLE 7.4 QI Method Examples

METHOD	DESCRIPTION	PROJECT EXAMPLE
DMAIC (Define, Measure, Analyze, Improve, Control)	Five-step process to define the problem and goals, measure processes objectively for baseline characteristics, analyze with root-cause analysis, improve process by addressing root cause, and control the improvement for sustainable change.	Shi et al. (2022) Sustaining SSI Improvements
PDSA (Plan-Do-Study-Act)	Four-step cyclic process to plan an improvement, do the process, study its success, and act to inform a new cycle based on the study phase.	Balla et al. (2018) Decreasing Central Line Infections
PDCA (Plan-Do-Check-Act)	Similar process (precursor) to PDSA, focusing on checking progress and adjusting behavior accordingly.	He et al. (2022) Nursing Quality Endoscopic Mucosal Dissection
Balanced Scorecard	Management tool that creates measures that involve customers, internal processes, and organizations.	Chorney et al. (2021) Improvement of Tracheostomy Outcomes
Fishbone Diagram	Visualization tool to establish factors influencing various components of a problem (i.e., measurement, materials, methods, environment, manpower, and machines).	Kaemingk et al. (2022) Improving NICU Discharges
FMEA (Failure Mode and Effect Analysis)	Attempt to find possible defects/problems/failures before they occur and the consequence of that failure.	Kammoun et al. (2021) Improving Sterilization Processes

QI, Quality improvement.

can transition into the improve phase. This step involves implementing changes to ideally improve upon the root cause of the problem defined. Although this step can be implemented in a variety of ways, it is important to remember that "interventions relying on human memory (education, pocket cards, policy changes, email reminders) may be appropriate, but will be weaker than those that are tied directly to process flow (hard stops in ordering, electronic alerts)."[77] Finally, the project can move into the control phase. This is a unique aspect to this model, as it specifically identifies how you will have sustainable change over time and establish tracking of the performance of the project. Implementing the DMAIC methodology can improve the value of healthcare services by increasing quality.[77,78]

FUTURE DIRECTIONS

The EHR is an ever-growing and changing environment. Use of its data and data abstraction have become increasingly complex. We have yet to see database registries that use natural language processing as their entire ascertainment of automatic data collection. But the future is near, as we are seeing an emergence of Cerner Real World Data collection and use.[79] These data require extensive cleaning and modifying before use with research or quality, but once these processes are in place, we will see an explosion of use that allows for live data updates and extraction.

A demand for improved and more expansive quality and safety training and education has been seen across medical schools and residencies. As more QI initiatives are implemented and these processes become standard of care within our workplace, surgical training must include QI education.[80] Domains including "background and methodology of improvement science and nontechnical skills such as teamwork and professionalism" were advocated as necessary components of a surgical quality curriculum.[81]

Another aspect of quality that needs continued work and evaluation is intrahospital performance by patient subgroups.[82] ACS NSQIP provides reports on subspeciality, disease, or procedures, but variations exist within subgroups of patients. Berian et al. showed significant differences between elderly/nonelderly, renal insufficiency/normal renal function, cancer/noncancer, and emergency/nonemergency patient cohorts. This provides a huge potential framework for future quality endeavors within individual hospital systems and potentially nationwide.

One of the largest challenges that remain is the implementation of QI initiatives.[19] Although individual collaboratives have been successful, how to translate and implement these processes nationally remains difficult. One place to consider starting has been proposed to include QI training in surgical residency curriculum.[83] The American Pediatric Surgical Association (APSA) has implemented a Quality and Safety Toolkit to share and disseminate their QI resources and initiatives nationally. Much more work and research are needed to allow for dissemination and implementation of QI initiatives nationally. In addition, expanding the development and support for quality collaboratives can lead to successful implementation.[84] Insurance companies have funded these levers for QI in the past; however, this has not proven to be a sustainable and generalizable approach. State and federal funding may be required to further these efforts.[19]

Lastly, quality initiatives need to avoid "teaching to the test" (where providers focus only on measures of quality they will be judged on and ignore other important aspects of care), unintended consequences of provider profiling (such as providers "cherry-picking" patients and cases), and issues related to measurement and QI prioritization and redundancy as the burden of measurement grows.[4]

CONCLUSION

Quality measurement must remain reliable and accurate to improve surgical care and reduce costs in the United States. Surgical quality assessment has progressed and has become essential to every surgeon's career. Therefore, it is important that measurement and implementation approaches continue to expand and evolve to adapt to the demands of surgical care.

CHAPTER 8

Patient-Reported Outcomes

Mariam N. Hantouli, Giana H. Davidson, and Anne P. Ehlers

OUTLINE

Introduction
  Why Patient-Reported Outcomes
Development of Patient-Reported Outcomes Instrument
  Conceptual Framework
  Target Population
  Item Generation
  Cognitive Interviews
  Anchor-Based Versus Distribution-Based Approach
  Reliability and Other Validity
Use of Patient-Reported Outcomes in Research Trials
Use of Patient-Reported Outcomes in Clinical Settings
  Improving Clinical Care
  Digital Health
  Shared Decision-Making
  Patient-Reported Outcomes and Promotion of Equitable Surgical Care
Limitations of Patient-Reported Outcomes
Conclusion

INTRODUCTION

One of the most time-honored traditions in surgical care is the careful collection and assessment of outcomes after surgery. Tracking outcomes after surgery can be used to improve patient care daily in the clinic or hospital or as part of larger assessments intended to improve population-level health, quality, and equity of access and care delivery. Different stakeholders may prioritize different outcomes. Traditionally, clinical outcomes including complications or mortality rates have been the primary metric to assess the quality of the operation. Cost of care and the financial impact of clinical care are also important components when evaluating quality. However, this can often leave out important components of patient care such as the impact on their ability to perform daily activities, their quality of life (QoL), or the overall patient experience.[1] For example, a particular operation may result in low risk of trackable surgical complications but may result in other impacts to the patient (e.g., nausea, decreased function, chronic pain) that worsen overall QoL after an operation. In these cases, traditional metrics might have told us that surgery was "a success" (e.g., the patient lived and did not have an American College of Surgeons National Surgical Quality Improvement Program [ACS NSQIP]-identified complication), but the patient may report they regret ever consenting to an operation. Consequently, there is an increasing focus on collecting and implementing patient-reported outcomes (PROs) in surgical care and research.

PROs are defined as "any report of the status of a patient's health condition that comes directly from the patient, without interpretation of the patient's response by a clinician or anyone else."[2] They improve the health and satisfaction of patients and are increasingly being used in routine clinical practice and in clinical research trials.[3] PRO monitoring has now been shown to improve early symptoms detection, patient-clinician communication, QoL, function, treatment duration, and survival and to decrease readmissions and emergency department visits.[4–8] PROs are often measured and collected using PRO instruments or questionnaires. Clinical teams have collected this important information informally. One clinical example is the pain scale, scored from 1 to 10. Examples of formal collection instruments include general instruments such as the European Quality of Life–5 Dimensions (EQ-5D) questionnaire,[1] which asks about overall functional QoL across multiple health domains; system-specific instruments such as the Gastrointestinal Quality of Life Index (GIQLI),[9] which asks about the overall gastrointestinal QoL; and condition-specific instruments such as the Diverticulitis Quality of Life (DV-QOL) instrument, which specifically asks patients about QoL related to diverticular disease.[10] The selection of a specific PRO instrument may depend on the purpose of asking, availability or accessibility of the instrument, the patient population, or prior research.

This chapter introduces the use of PROs in clinical practice and in health services research. We will begin by describing the rationale for using PROs overall as well as applications in clinical and surgical research. We will then provide an overview of how to develop a PRO instrument, including insights useful for appraising the validity or utility of existing instruments. We will then give real-life examples of when and how PROs have been used in both the research and settings. Finally, we will discuss the limitations of PROs and future research.

Why Patient-Reported Outcomes

PROs allow providers, researchers, and other stakeholders to gather information about patient treatment and outcomes that is not available in clinical records or administrative databases.[11] Information such as diagnosis, intervention (e.g., surgery, medications), and outcomes of treatment can be ascertained from clinical registries such as the ACS NSQIP[12] or claims files such as the Medicare Provider Analysis and Review (MedPAR).[13] Although information from these multiple sources can triangulate to give a robust view of the risk of mortality or complications, they still do not provide an understanding of the patient experience, such as how much pain medication they required, whether they had to take time off of work, and so on. These are important factors that patients consider when determining treatment plans.

Questions such as "What is your pain on a scale of 1 to 10?" are commonly asked by healthcare teams. Answers to these questions provide valuable information that can be used to guide care. Formal PRO instruments quantify and codify responses to such questions. Importantly, responses can be documented and saved at different points in time to guide care and track progress or progression over time. Including the patient's voice in evaluation is an important piece of the overall clinical picture to understand how a given intervention is directly affecting the patient. For instance, to demonstrate how these different tools can describe different aspects of a disease, consider a patient with diverticulitis. A research team may report four hospitalizations over a year using data from MedPAR (an administrative database for Medicare beneficiaries including inpatient hospital services). ACS NSQIP may reveal the presence of a surgical site infection following sigmoid resection. Clinically, the pain scale in a progress note can quantify pain from a patient's perspective at a single point in time. The DV-QOL would allow research teams to understand the impact on patient QoL including concerns about diverticulitis and the psychological, social, and behavioral impact of diverticulitis from the patient perspective. Each of these holds a distinct value and role with their significance varying based on the specific needs and perspectives of stakeholders at various points in time.[14]

The evolution of bariatric surgical research is an example of the integration of clinical outcomes and PROs to provide a holistic view of care and support shared decision-making. In the 1990s and early 2000s, bariatric surgery was considered a high-risk surgery with significant patient mortality and morbidity. Therefore, reducing death and harm was a pressing issue to address and track for researchers, patients, and clinical teams. In the case of bariatric surgery, a significant body of research led to improvements in care, and now bariatric surgery is one of the safest operations with an overall perioperative mortality rate of 0.03% to 0.2% and a less than 6% risk of 30-day adverse events.[15] It should be noted that these favorable statistics occur in the setting of a population of patients with multimorbidity including hypertension, obstructive sleep apnea, type 2 diabetes mellitus, and other metabolic sequelae of obesity.

However, most patients undergo bariatric surgery to lose weight and improve their overall health. Although certain health metrics can be tracked in clinical registries and claims databases, key metrics (e.g., weight loss, abdominal pain, QoL) can be evaluated only by directly asking the patient. In this sense, PROs augment already available metrics to improve the outcomes for patients. To address this need, there has been an increasing focus both by national groups such as the Metabolic and Bariatric Surgery Accreditation and Quality Improvement Program (MBSAQIP) and regional groups such as the Michigan Bariatric Surgery Collaborative (MBSC) to collect and report on PROs such as gastroesophageal reflux disease severity, mental health outcomes, and weight loss over time.[16–19] As we continue to evolve, it becomes clear that PROs should ideally be collected simultaneously as we collect clinical outcomes, which may lead to more efficient evaluation of the impact of different interventions.

DEVELOPMENT OF PATIENT-REPORTED OUTCOMES INSTRUMENT

The establishment of an effective PRO instrument requires an understanding of the underlying theoretical framework, the specific concepts it addresses, and the psychometric principles it stands on.[20] There are several theoretical frameworks commonly used in the development and evaluation of health-related PRO instruments. For example, the community-centered theory, which is central to the design of the 36-Item Short Form Survey (SF-36), suggests that diseases influence a layered hierarchy of functional domains, beginning with physical functioning and extending to broader implications on emotional and psychological functioning and performance in social roles. Within this framework, the physical and symptomatic dimensions are often foregrounded, showing strong associations with psychological and role-specific domains.

The purpose of a PRO instrument influences its design. Instruments aimed at general screening have different characteristics compared with those aimed at evaluating response to treatment or variations of health status over time. Thus, developers select relevant concepts and domains that the instrument should measure (Table 8.1).[2]

TABLE 8.1 **Steps to the Iterative Process of a PRO Instrument Development**

Step 1: Hypothesize conceptual framework	Define the purpose of the PRO instrument
	Identify the intended population
	Conduct a thorough literature review
	Collaborate with experts
	Define the hypothesized concepts and potential outcomes
Step 2: Refine conceptual framework	Collaborate with patient advocates
	Integrate diverse perspectives
	Establish comprehensive concepts and domains
Step 3: Draft instrument	Create initial items based on identified concepts and domains
	Determine instruments' characteristics (response options, recall period, scoring)
	Determine mode(s) of administration
	Pilot test draft instrument
	Establish content validity
	Document draft development
Step 4: Confirm conceptual framework	Finalize the conceptual framework
	Identify a diverse target population, external validity
	Conduct patient interviews, and focus groups
	Modify instrument and response scales
	Document actions taken to refine the instrument
Step 5: Assess measurement properties	Assess instrument's content validity test-retest reliability, construct validity, and sensitivity to detect change
	Finalize instrument items, scoring, format, procedure, and training materials
	Maintain detailed documentation
Step 6: Collect, analyze, and evaluate data	Prepare statistical analysis plan
	Identify responder definition
	Prepare statistical analysis plan
	Collect and analyze data
	Evaluate outcomes
	Document interpretation of outcomes in relation to the purpose of the instrument
Step 7: Modify instrument	Change wording of items, populations, instruments' characteristics, and mode of administration
	Translate and culturally adapt to other languages
	Establish content validity in other languages
	Evaluate modifications
	Maintain detailed documentation

PRO, Patient-reported outcome.

Adapted from Center for Drug Evaluation and Research, Center for Biologics Evaluation and Research, Center for Devices and Radiological Health. *Guidance for Industry: Patient-Reported Outcome Measures, Use in Medical Product Development to Support Labeling Claims.* Rockville, MD: U.S. Dept. of Health and Human Services, Food and Drug Administration, Center for Drug Evaluation and Research, Center for Biologics Evaluation and Research, Center for Devices and Radiological Health; 2006.

Conceptual Framework

Concepts are the most overarching elements that the PRO instrument aims to evaluate. Within these concepts, domains are defined to provide more specific areas of focus. Specific item development then revolves around these domains, ensuring that each individual question or statement effectively gauges the targeted domain within the broader concept. The key first step in developing a PRO instrument is to ensure that the items in the tool align well with the overall concept that is to be measured. To do this, developers hypothesize an initial conceptual framework guided by literature reviews and expert input, which then undergoes refinement through patient interviews, focus groups, and cognitive qualitative interviews. This final framework outlines the relationships among overarching concepts, domains, and individual items, along with the scores generated. It evolves through both developmental stages and empirical validation. Once employed in clinical trials, additional data affirm the framework's validity, further solidifying the observed interrelationships among items and domains. For example, Fig. 8.1, adapted from Spiegel et al., illustrates the conceptual map for the development of the DV-QOL instrument, a disease-targeted QoL instrument for chronic diverticular disease. The map for the DV-QOL instrument shows the complexity of the patients' experience with diverticular disease, encompassing a range of physical symptoms, emotional states, social impacts, and disease-specific cognition or concerns.[10]

Target Population

The population for which the PRO instrument is designed is a critical determinant of the tool's generalizability and clinical relevance. Developers should consider age, cognitive abilities, comorbidity profiles, and other demographic or clinical variables relevant to the condition studied. An analysis of demographic characteristics such as sex, gender, race, and socioeconomic status should also be undertaken. Variations in these demographic factors can influence PRO scores; therefore, understanding these variations is necessary for comprehensive result interpretation and to establish the instrument's external validity. Clearly defining the inclusion and exclusion criteria ensures that the target population aligns with the broader population of individuals with the disease of interest, enhancing the PRO instrument's applicability and generalizability. Failure to align the target population with the broader population can lead to inaccuracies in interpretation and can affect the instrument's generalizability. Recruitment efforts should support equitable representation in the target population.

Item Generation

Item generation starts with a literature review to identify preexisting scales, items, and domains pertinent to the disease-specific QoL measures. This review also highlights gaps in existing instruments, guiding the creation of additional items for the new PRO instrument. Experts, such as clinicians, academic researchers, and patient advocates, are consulted to assess the suitability of the proposed domains, refine or expand the list of items, and offer practical advice on using the instrument. Target patient populations contribute through focus groups and interviews, providing insights on item wording, clarity, and the overall utility of the instrument. This process should ensure representation across various factors including age, sex, gender, race, ethnicity, and language of the range of people that experience the disease. When attempts at diversity fail, there can be profound downstream consequences on future protocols or policies that are, in essence, created without the voice of subpopulations who are affected by the disease but are historically

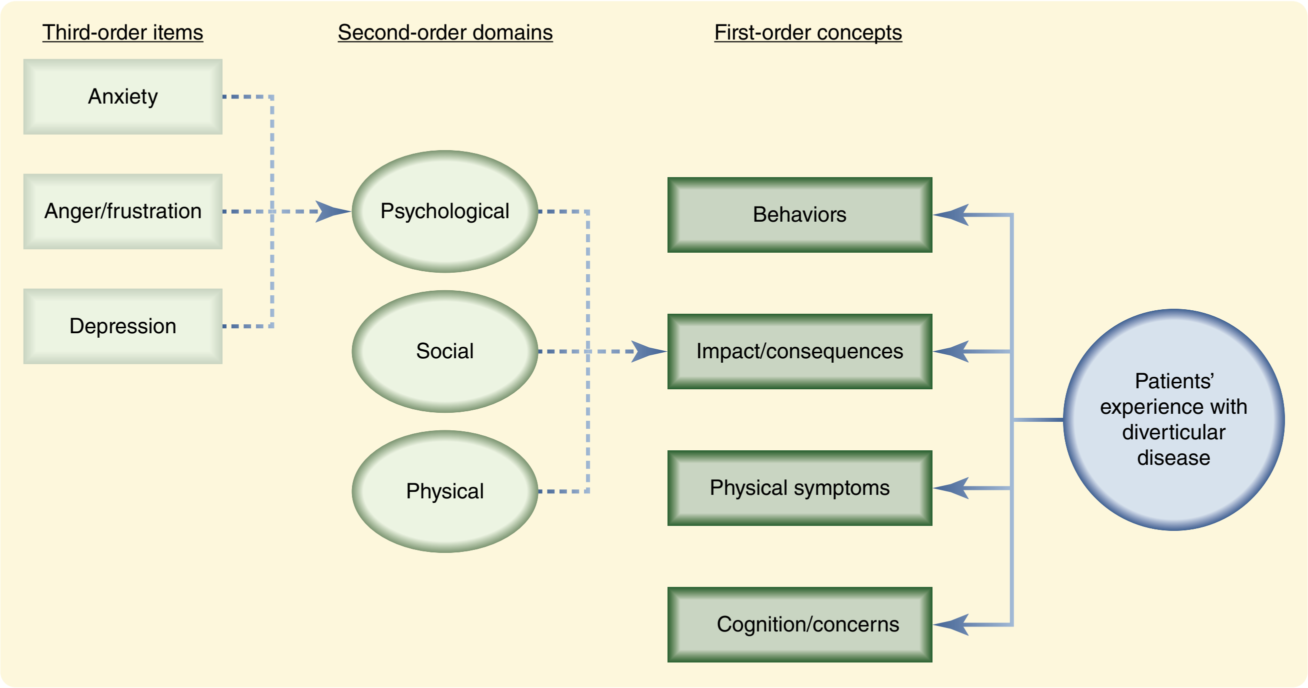

FIGURE 8.1 The map is organized around first-order concepts. Here it shows four first-order domains: (1) physical symptoms, (2) cognition/concerns, (3) behaviors, and (4) impact/consequences. These first-order concepts are further divided into second-order domains. For instance, within the first-order concept of "impact/consequences," psychological effects form a second-order domain. Finally, individual third-order items like feeling anxious, frustrated, or depressed are used to evaluate these second-order domains.

and/or currently marginalized or excluded from research initiatives. There are a number of examples in which medical treatment indications are affected by race or by other factors as a direct result of how they are constructed.[21,22] It is critical to ensure that the item generation process includes voices from diverse lived experiences, ensuring representation of heterogenous racial, ethnic, and socioeconomic populations. This inclusive approach, along with applying an equity-focused lens to qualitative sampling methods, is important to help reduce research biases and potentially address their subsequent impact on policy.[23,24]

Despite regulatory guidance advocating for diversity, there is often a lack of diverse representation in clinical trials. This is due to a combination of factors including mistrust of research and medical institutions, overly restrictive inclusion criteria, and limited enrollment opportunities that are often constrained to a specific setting like urban academic centers. Clinical trials gathering PROs introduce biases when certain patient groups are systematically and often unintentionally underrepresented or not enrolled. This exclusionary practice perpetuates inequitable care and undermines the validity of the research. It also significantly restricts our understanding of the different effects of treatments or diseases and the varied aspects of QoL as experienced by different individuals. The consequence of this exclusionary practice is a significant reduction in the applicability of evidence needed for formulating inclusive clinical guidelines, making informed regulatory decisions, and shaping effective and equitable health policy for populations that are often already minoritized.[25]

Using an intersectionality framework[26] (i.e., one that considers multiple aspects of a person's lived experience or identity) is critical in study design to acknowledge the layered experiences of patients and the different effects of disease and treatment options. For instance, hysterectomy is often performed for vaginal bleeding, pelvic pain, and uterine bulk after failure of medical therapy. However, there is wide variation in rates of hysterectomy by race, insurance status, and geography,[27–29] and it is unclear if this variation in access to surgical care represents differences in symptom severity, preferences of patients, and/or biases within the healthcare system. Leveraging data across multiple sources, researchers were able to construct a composite symptom severity index to examine how symptom severity may vary by groups of interest, supporting either a clinical need for increased access or systemic retraining on how symptom severity may be differentially assessed and acted on.[29] Limiting PRO data from patients who are readily or usually included in research (e.g., White, English-speaking, insured, adult, male), regardless the sample size, is likely to limit our understanding of the effect of diseases and treatment options on QoL and thus the evidence base needed to provide clinical recommendations, create regulatory and reimbursement decisions, develop clinical protocols, and inform health policy.

Once items have been generated, they must be tested to ensure that all essential aspects of the target concepts are represented. This process is known as achieving *conceptual saturation,* where no additional information would contribute further understanding. Detailed documentation should be maintained throughout to substantiate content validity, including techniques used in item generation, population studies, and cognitive interview summaries. Content validity is the degree to which an instrument accurately measures the intended concept. It is established through qualitative research that ensures items and domains are comprehensive and relevant to the measurement concept, specific population, and intended use. Before evaluating other forms of validity (e.g., construct validity) or reliability, content validity must be established. For clinical trials involving multiple languages, additional cognitive interviews are conducted in each language to validate the content. Finally, patients offer direct feedback on the questions under consideration, the language used, and the overall utility of the instrument through focus groups or interviews.

Cognitive Interviews

Cognitive interviews ensure that the instrument's items and response scales are appropriately conceptualized and understood by the targeted patient population. These interviews typically involve a scripted dialogue with patients to assess their understanding of each item, the appropriateness of the response options, and the recall period specified in the instrument. Alongside these elements, readability and, if applicable, usability testing processes should be used to ascertain the instrument's ease of use and accessibility for the target population.

The iterative nature of cognitive interviews aids in affirming the content validity of the PRO instrument. By periodically repeating these interviews, researchers can ensure that the instrument's conceptual framework, response scales, recall periods, and instructions are aligned with patients' understanding, experiences, and interpretation. Consequently, it is advisable to compile a comprehensive cognitive interviewing report. This report should detail the interview script, transcripts, analysis of the cognitive interviews, and any subsequent actions taken to refine the instrument. This document serves as a resource for both internal review and for submission to peer-reviewed journals.

Anchor-Based Versus Distribution-Based Approach

An anchor-based approach uses an "anchor," which is an external and easily interpretable benchmark or measure, to contextualize changes in PRO scores. An anchor can be a clinical outcome, a separate well-established scale, or any other relevant metric that provides a concrete reference point against which changes measured by the PRO can be assessed. The anchor should be easier to understand than the PRO itself. For example, in a study assessing QoL changes over time in patients with diverticular disease, an anchor can be a specific question to assess satisfaction with gastrointestinal overall health. This specific question offers a direct, easily understandable point of comparison for interpreting the nuanced QoL changes captured by the PRO (e.g., DV-QOL).[30]

The distribution-based approach defines the changes in PRO scores by analyzing the distribution of these scores within a patient population. Statistical methods, such as between-person standard deviation or standard error of measurement, are used to categorize the magnitude of change in PRO scores as small, moderate, or large. These statistical categorizations can be used alongside the anchor-based estimates to add confidence in defining responders. This approach helps gauge the relative significance of PRO score changes and should be considered as a supportive method for defining responders because statistical definitions of change might not always directly translate to clinical significance. Therefore, any conclusions drawn from the distribution-based approach should be contextualized within the broader clinical picture and patient experience.

Reliability and Other Validity

Other measurement properties of a PRO instrument include test-retest reliability, construct validity, and the instrument's sensitivity to detect change. Test-retest reliability ensures that the PRO instrument provides consistent, reproducible estimates of true treatment effect over time, a feature essential in longitudinal studies or clinical trials. To assess test-retest reliability, researchers should administer the PRO instrument to the same group of patients at two different time points. The time interval between the two administrations should be carefully chosen based on the stability of the condition being studied and the potential for participant recall. Statistical methods such as the Intraclass Correlation Coefficient (ICC) and Pearson's correlation are commonly used to quantify the degree of agreement between the two sets of scores. An ICC or Pearson's correlation value closer to one indicates high test-retest reliability. It is important to choose the statistical method that aligns with the data distribution and fulfills the assumptions underlying the method.

USE OF PATIENT-REPORTED OUTCOMES IN RESEARCH TRIALS

PROs are a critical and an increasingly used component of clinical research trials in surgery.[31] These outcomes are crucial for guiding surgical decision-making and ensuring that surgical interventions align with patients' preferences and priorities. PROs provide valuable insights into the patient experience, helping patients, their caregivers, and surgeons make more informed choices regarding surgical techniques, interventions, risks, and outcomes. PROs are typically collected through questionnaires or interviews. In general, a PRO instrument should be brief, simple, and understandable to patients with diverse educational and cultural backgrounds. The chosen research PRO should be validated for repeated use and measure the important patient outcomes for the disease and the procedure. They have been shown to be sensitive to both acute and chronic conditions and symptoms and function in the patient population of interest.[32] The engagement of key stakeholders including patients, caregivers, and policymakers should be considered when choosing PRO instruments in clinical research trials.[33,34]

PROs are especially important in the context of preference-sensitive conditions. Preference-sensitive conditions are those for which multiple treatment options exist, each with its own set of potential benefits, risks, and costs. These trade-offs could affect a patient's QoL, disease recurrence, time away from work, work productivity, caretaking responsibilities, and survival. Thus, a standardized "one-size-fits-all" treatment approach does not exist; rather, treatment decisions should be individualized to reflect a patient's unique values and preferences. The optimal treatment choice for a patient should be made after the patient has been fully informed about their options and the implications of each. This decision should be guided by the patient's personal preferences and goals. For instance, the treatment of early-stage breast cancer may include a mastectomy or lumpectomy with adjuvant therapy. Although clinical trials have shown that survival is similar between approaches, other clinical and PROs favor one or the other treatment option. A person who chooses a mastectomy will experience the loss of the breast and might consider reconstructive options. For those who have a lumpectomy, they may keep their breast, but the trade-offs may include radiation or chemotherapy and a higher risk of local recurrence. The decision for treatment in these conditions should be made only after discussion of the evidence-based information regarding available options. Shared decision-making considers the patient's values and preferences, the clinical team's knowledge and experience, and allows for the patient and their caregivers to work with the clinical team to make decisions that align with patient's priorities at that time. Clinical- and patient-reported outcome data can be used to create decision aids to support shared decision-making. When compared with usual care, they have been shown to improve knowledge and decrease decisional conflict for a range of preference-sensitive surgical decisions including the choice between mastectomy or breast-conserving surgery.[35]

The incorporation of patients' experiences and perspectives on their health and the effects of different treatments allows for a more comprehensive understanding of treatment options and outcomes. Consequently, the integration of PROs in clinical research empowers healthcare professionals and patients to make more informed choices, advancing patient-centered care and enhancing the relevance and impact of research outcomes on current clinical practice. Unfortunately, decision aids are limited and often used primarily in outpatient and elective settings. Tools to enhance communication, especially in the urgent or emergent setting, are important. Structural frameworks, such as "best case/worst case," help patients and their caregivers organize information to support decision-making,[36] and PRO from clinical research trials offer important information on outcomes that matter to patients and their families.

USE OF PATIENT-REPORTED OUTCOMES IN CLINICAL SETTINGS

PROs can provide additional and important insight into patients' experience of symptoms, their QoL, and function; their values; preferences; and goals for healthcare. This information improves clinical care and patient experience and supports shared decision-making conversations. In this section we will provide various examples of how this can be implemented in real-world settings.

Improving Clinical Care

Although the assessment of a patient's experience is captured informally in clinical practice, there is increased enthusiasm, expansion to applications, and policy facilitators for incorporating these measures into clinical practice.[37,38] In this setting, PROs are typically used to gauge how well or unwell the patient is doing. Favorable PROs (e.g., improved pain, fewer symptoms) can indicate that the current plan of care is working, whereas unfavorable PROs (e.g., worse pain, more symptoms) may be a signal to the provider that the care plan needs to be amended. For example, excellence in orthopedic care requires an understanding of a patient's history of musculoskeletal pain and functional limitations. The Function and Outcomes Research for Comparative Effectiveness in Total Joint Replacement (FORCE-TJR) describes the importance and practical implementation guidelines for integrating PRO assessment into orthopedic clinical practice.[39,40] In practice, mean scores on standardized questionnaires can be difficult to interpret, and clinicians need to know what a clinically relevant treatment success looks like when using scores over time. The minimal clinically important difference (MCID) and patient acceptable symptom state (PASS) were created to address this issue. The MCID is defined as "the smallest change that is important to patients," and PASS is the "score below which patients consider themselves well."[41,42] However, in practice, remember that individual outcomes are unique to each patient, and clinicians should evaluate and interpret the treatment effects in context of that individual's clinical course. Group-based MCID scores should not be used to determine whether individual patients have exceeded a "meaningful" change.[43]

PROs are increasingly used in value-based healthcare initiatives.[44,45] Although many assessments remain informal, unable to be tracked across health systems, and may or may not be recorded in the patient's medical record, there are some instances in which PRO assessments have been formally integrated into clinical care for purposes of improved decision-making and for reimbursement. Surgical treatment of low back pain is an example where this has occurred.[46] In 2010 low back pain was recognized as the most common diagnosis contributing to disability in the United States, costing the United States healthcare system more than $26 billion dollars annually. Many patients with low back pain lack any clear physiologic or anatomic abnormality that could be causing their pain. Additionally, there is significant variation in care for patients with low back pain ranging from physical therapy to opioid medication to lumbar fusion surgery. At the same time, treatment for this condition has intensified with a significant increase in the overuse of non–evidence-based treatments such as injections and advanced imaging. To address this, the Bree Collaborative, a Washington State–based organization focused on identifying and recommending evidence-based strategies for conditions with high levels of unnecessary treatment and poor patient outcomes, created a bundle of recommendations specifically related to treatment of low back pain. Two of the key recommendations that were directed at hospitals, providers, payers, employers, and health plans were (1) assessment of functional status over time using the Oswestry Disability Index and (2) requiring the use of screening tools such as the STarT Back tool or the Functional Recovery Questionnaire (FRQ) to identify which patients would be most likely to respond to routine care. These recommendations were tailored to each stakeholder such that they covered all aspects of care from assessment in the clinic to negotiation within networks to determine payments. Requiring integration of PROs into clinical assessments for low back pain resulted in changes to benefit offers in more than 50% of health plans and the development of shared decision-making tools for persons with low back pain.[47] This example provides a powerful framework for thinking of how we can integrate assessment of PROs into efforts to improve clinical care. This is particularly true for elective, preference-sensitive conditions in which there is equipoise between multiple treatment options.

Digital Health

Mobile health or "mHealth" refers to the rapidly expanding practice of medicine aided by mobile devices. This is often related to communication provided digitally through computers, mobile phones, and patient monitors worn at home. Significant opportunities exist to enhance early symptom detection and intervene sooner preventing costly and potentially harmful downstream complications.[8] Yet, there remain limitations in the implementation of patient-generated health data in busy clinical surgical practices including patient and clinical team expectations of use and response times.[48] Successful implementation of PRO monitoring tools will need approaches that optimize engagement and buy-in of patients, clinicians, and staff. While the benefits are not controversial, it will likely require reorganization of workflow and personnel across health systems.

Chronic groin pain occurs in up to 25% of persons undergoing groin hernia repair and is an important outcome to consider for persons with small, minimally symptomatic hernias. The Carolinas Equation for Quality of Life (CeQOL) is a mobile app that uses data from nearly 2000 individuals to predict the risk of chronic groin pain after groin hernia repair. This can be used as an educational tool for patients in preoperative discussion on their risk of discomfort or pain 1 year after surgery.[49,50]

Shared Decision-Making

Use of PROs is critical when having shared decision-making conversations with patients. Particularly for conditions in which there is equipoise between two or more treatment options, patients often want to know what the impact to their daily function will be, how it might affect their ability to participate in work or other activities, or how it might impact their mood. Lack of inclusion of PROs in these conversations may also lead to decisional regret, where patients wish they had chosen another operation or feel distress over the decision they made because they were not fully informed of the potential outcomes.

To illustrate this point, we will describe how a focus on PROs changed management for appendicitis, one of the most commonly performed operations around the world. Beginning in the late 1800s, surgical appendectomy became the mainstay of treatment for acute appendicitis. However, over the next 50 to 60 years it became evident that nonoperative treatment with antibiotics and close observation may be a viable treatment strategy for this disease.[51] In 1995, the first randomized controlled trial was performed to compare operative and nonoperative treatment of acute appendicitis.[52] Over the next 20 years, this trial was repeated in different settings; each of the trials showed that antibiotics as an initial treatment strategy appeared to be safe but that patients experienced recurrent appendicitis in up to 35% of cases and patients received an appendectomy in up to 60% of cases.[53–57]

Although these trials contributed significantly to inform the *safety* of nonoperative management, patients and surgeons continued to have questions regarding treatment strategies including long-term pain, time away from work or school, and other QoL-related metrics.[58] To address these, the Comparing Outcomes of Drugs and Appendectomy (CODA) trial included stakeholder engagement in the development of the trial to ensure inclusion of important primary and secondary outcomes for key stakeholder groups.[59] The primary outcome for CODA was a 30-day patient-reported health status as measured by the EQ-5D.[24] Using a pragmatic study design, the study investigators found that when using patient-reported health as the overall outcome, antibiotics were noninferior (i.e., not worse than) to surgery on the basis of 30-day EQ-5D scores, participants and caregivers missed less time at work, and, in many cases, patients could avoid a hospitalization with antibiotics.[60,61] The focus on patient experience is the foundation for development of shared decision-making tools that may help improve communication and understanding to support patients to make health decisions that best align with their personal goals and preferences. Information from clinical trials centering patient experience can be implemented directly into clinical practice to enhance shared decision-making discussion. In places like the emergency department, the clinical teams need efficient tools to account for their workload and the busy environment. Patients are often in the emergency department without their usual caregivers or usual healthcare team available to help support them in making decisions. Decision support tools (e.g., appyornot.org) may help support patients and clinical teams in providing efficient and patient-centered care in a way that information can be shared with people outside the emergency setting and revisited. Based on a person's characteristics, circumstances, and priorities, for appendicitis treatment, the management paradigm is changing, and while antibiotics will be an optimal treatment for some, it will not be for all patients.

Shared decision-making should include the following components: (1) seeking to understand patients' goals and views about treatment options; (2) transferring information about the diagnosis and the technical aspects of each treatment options; (3) ensuring understanding, recognizing the risks or downsides to surgery, and allowing time for patients to ask questions[62]; (4) supporting patients in exploring and sharing their preferences based on evidence; and (5) sharing treatment recommendations within the context of uncertainty in the clinical decision-making process.[63]

Despite evidence that shared decision-making improves patient experience and clinical outcomes and decreases regret, barriers to implementation have halted its growth. Clinicians frequently point to time constraints as a predominant obstacle to integrating shared decision-making processes and tools into routine clinical practice. However, the evidence regarding the time burden is conflicting.[64,65] Undoubtedly, successful implementation of PROs into clinical practice lies in filling evidence gaps for enhancing communication and the education of surgeons in effective communication strategies to provide essential support to patients in decision-making.[66–68]

Patient-Reported Outcomes and Promotion of Equitable Surgical Care

Assessment and integration of PROs into clinical care has an important role in promoting equitable care for persons undergoing surgical evaluation. There are several surgical diseases for which treatment is determined primarily by patient-reported symptoms such as pain, function, or QoL. Examples include elective hernia repair, hysterectomy, spine and joint surgeries, cholecystectomy for biliary colic, and peripheral vascular interventions for claudication. For many of these surgical conditions there are well-described differences in treatment and outcomes by patient sex, race, or socioeconomic status. The inclusion of PROs with traditional outcome measures has the opportunity to improve both quality and equity of surgical care.[69] However, this will require the development, implementation, and interpretation to center health equity and include experts in equity and disparity research.[70] As an example, hysterectomy is one of the most common operations performed among females in the United States. Common indications for hysterectomy include pain, uterine bulk, and bleeding—all of which may be reported by patients, but variation in reported severity may impact access to workup and surgical care.[71] Surgeons and patients may not agree in the indications for treatment,[72] and providers may not consider these symptoms equally across all patients (i.e., there is bias in interpretation). In one study evaluating hysterectomy rates among premenopausal females, Robinson et al. found that, compared with White patients, Black and Hispanic patients report worse symptoms (which should drive higher rates of hysterectomy) but similar rates of surgery, which may indicate undertreatment.[73] Recognizing bias in the use and the development of PROs is crucial to improve inequitable care delivery across diverse populations

LIMITATIONS OF PATIENT-REPORTED OUTCOMES

Despite the many strengths of PROs for improving clinical care and research, there are key limitations related to the inclusivity when instruments are designed, developed, and interpreted. Understanding the limitations should improve clinicians' and researchers' interpretations of the PROs in research and in the clinical setting. As discussed previously, development of PRO instruments is an intensive process requiring careful input from all relevant stakeholders. Because PRO instruments are typically developed for purposes of research or quality improvement, they are often developed by clinicians or researchers and include high-level language and complex sentences that may make understanding and completing them difficult for people rather than using the language of the patient population that has the disease.[74–76] The readability, comprehensibility, and cultural appropriateness of instruments impact the development and use of PROMs, and the Outcome Measures in Rheumatology Equity Work Group has been working to develop framework and guidelines for cross-cultural adaptation of PRO tools.[77,78]

It is important to consider the overall inclusivity of PROs assessments. Persons from underserved populations are less frequently represented in clinical trials, and this becomes especially problematic when clinical trials include PROs in their outcomes assessments. For example, if the clinical trial in question does not include a diverse patient population, then the PROs reflected in their findings will be biased and may even be harmful. This will further perpetuate inequities in care as these findings are applied to the population, not considering the differential outcomes among underrepresented persons.

PROs are limited to the experiences of patients who are included in the data collection process, often leading to an overrepresentation of populations who are White, English-speaking, more literate about health, able to access digital technology, and insured. The experiences and perspectives of those not enrolled are simply invisible to research teams and policymakers. This erasure leads to an incomplete understanding of the effectiveness of a treatment, the impact of disease burdens, or surgical procedures. Even when PRO data draw from a representative population, they often do not encompass the outcomes that matter most to some people, or they might rely on legacy measures lacking content validity or serving merely as proxies for another important metric. For instance, for people who are uninsured, unhoused, or living paycheck to paycheck, the financial burden of healthcare or the cost of childcare for an overnight stay in the hospital may be the most important determinant for decision-making. Yet, there is insufficient understanding of these out-of-pocket expenses and a lack of tools for discussing this with patients, despite evidence of the substantial impact of financial toxicity on surgical patients in the United States healthcare system.[79–83]

The expansion of PROs can improve individual patient care and engagement, yet, like all quality initiatives, it could also inadvertently widen the equity gap, particularly if improvements disproportionately benefit already advantaged populations.[80,84] The development, implementation, and interpretation of PROs are costly, and a commitment to centering equity and including patient stakeholders will require more time and financial investments from both funding agencies and health systems. However, investing in the development of tools and broad implementation of PROs in clinical care and research will enhance our understanding of patient experiences, treatment success, and how social determinants of health and clinical risk factors impact patients' access to care and QoL.

CONCLUSION

The use of PROs significantly contributes to understanding patients' experiences with health conditions, treatment options, and complications. PRO data facilitate a comprehensive evaluation of the burden of diseases and their treatment options on patients' QoL and experiences. Integrating PROs into shared decision-making discussions between clinicians, patients, and their caregivers will aid in ensuring that treatment choices align with individual patient needs and goals. Although PROs are critical, they represent only a part of the broader narrative of patients' experiences and are susceptible to biases in their development, implementation, and interpretation. Therefore, it is important to integrate different outcome metrics that reflect the social, economic, and environmental determinants of health, which significantly affect patients' experiences, access to care, and ultimate outcomes.

Ehlers AP, Hantouli MN, Davidson GH. Traditional measures of surgical outcomes only tell a portion of the patient story-who measures success? *JAMA Surg*. 2021;156:765-766.

A commentary on the need to integrate patient-centered outcomes into surgical outcomes assessment to reflect aspects of recovery and well-being most meaningful to patients.

Flum DR, CODA Collaborative, Davidson GH, et al. A randomized trial comparing antibiotics with appendectomy for appendicitis. *N Engl J Med*. 2020;383:1907-1919.

A large, pragmatic randomized clinical trial evaluating the comparative effectiveness of antibiotics and appendectomy for appendicitis through a comprehensive assessment of impact, including multiple patient-reported outcomes that reflect what matters most to patients. These outcomes are critical in guiding patient-centered treatment decisions.

Hantouli MN, Droullard DJ, Khor S, et al. Indications for surgical treatment of diverticulitis: factors that influence surgical decision-making for patients and surgeons. *Br J Surg*. 2022;109:1329-1330.

A prospective study highlighting key gaps in communication between surgeons and patients, emphasizing the need for more comprehensive, patient-centered approaches to improve shared decision-making and support patients in collaborating with their clinical team to make decisions that align with their priorities.

Hantouli MN, Khor S, Strate LL, et al. What's in a number? Assessing the burden of diverticular disease. *Ann Surg Open*. 2022;3:e202.

A prospective study demonstrating the importance of a patient-reported outcome instrument (i.e., the Diverticulitis Quality of Life instrument) in assessing the burden of diverticulitis on patients' quality of life and monitoring response to treatment.

Hasanov E, Caceres JOH, Maskens DA, Giles RH, Schmitt AM. Patient-reported outcomes: what really matters to patients? *Lancet Oncol*. 2022;23:e198.

A perspective calling for patient-informed PRO measures to reflect outcomes that matter to patients, support shared decision-making, and improve the relevance of clinical trial findings for patients with metastatic renal cell carcinoma.

Ortega G, Allar BG, Kaur MN, et al. Prioritizing health equity in patient-reported outcome measurement to improve surgical care. *Ann Surg*. 2022;275:488-491.

A commentary on the need to expand the development and use of patient-reported outcome measures that reflect the needs and experiences of all patient populations to improve individual care, patient engagement, outcome quality, and understanding of how social risk factors impact patients' surgical experience and postoperative quality of life.

Spiegel BM, Reid MW, Bolus R, et al. Development and validation of a disease-targeted quality of life instrument for chronic diverticular disease: the DV-QOL. *Qual Life Res*. 2015;24:163-179.

A foundational study developing and validating a disease-specific quality of life (QoL) instrument to assess the multifaceted impact of diverticular disease on patients' QoL, including physical, psychological, and social symptoms.

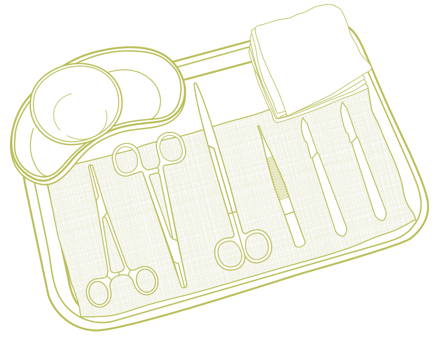
9 CHAPTER



Safety in the Surgical Environment

Aditi Balakrishna, Michael P. DeWane, Haytham M.A. Kaafarani, and Warren S. Sandberg

OUTLINE

Introduction
Establishing an Environment That Promotes Safety
What Major Specific Safety Concerns Exist in an Intraoperative Context?
  Sterility and Environmental Issues
  Surgical Management Concerns
  Anesthesia Concerns
Perioperative Events That Rely on Safety Culture for Identification and Management
What Structures Can Support Safety Culture?
Conclusions

INTRODUCTION

The ultimate goal of healthcare, including surgery, is to improve health. When a series of reports published in the 1990s provided evidence of high rates of serious adverse events (AEs) that resulted in harm to hospitalized patients, an inevitable cultural shift in the approach to healthcare delivery occurred. In its 1999 landmark report *To Err Is Human*, the Institute of Medicine[1] estimated that as a result of medical errors, 1 million people per year get injured, and 98,000 per year die. AEs occur in 3% of operative procedures and deliveries and are associated with a mortality rate of 5.6%. These occurrences account for 48% to 66% of AEs among hospital discharges and 12.2% of hospital mortalities.[2] Furthermore, 54% of surgical AEs were deemed to be preventable. In the past two to three decades, healthcare leaders, governments, and independent organizations have made patient safety a priority and have tirelessly worked to improve outcomes and decrease AEs. Despite these efforts, a recent retrospective cohort study across 11 Massachusetts hospitals suggested that one or more AEs occurred in 23.6% of all hospital admissions, with 30.4% of these being surgical or procedural, 22.7% deemed to be preventable, and 32.3% causing harm or requiring substantial intervention or prolonged recovery.[3]

To contextualize these figures as well as the larger concept of safety in the surgical environment, it is first necessary to understand what AEs are, how they are defined and identified, the methods and structures available to evaluate them, and what their economic impact is. The term *adverse event* refers to a negative, harmful outcome experienced by a person receiving healthcare; these events may or may not be errors, and they can be both preventable or not preventable. In surgical patients, these include the AEs common to all hospitalized patients—such as drug events, falls, missed diagnoses, deep venous thrombosis/pulmonary embolism, aspiration, respiratory failure, nosocomial pneumonia, myocardial infarction, and arrhythmias—as well as those specific to surgery, such as technical or intraoperative complications, wound infections, and postoperative bleeding.

Determining the incidence of AEs can be challenging. The most reliable prospectively collected data come from large multi-institutional registries such as the American College of Surgeons National Surgical Quality Improvement Program (ACS NSQIP) database. Using 2012–13 ACS NSQIP data, Freundlich et al. identified 9255 deaths among 1.2 million patients within 30 days (0.77%) after their index surgical procedures.[4] The most common causes of attributable mortality in this study were bleeding, respiratory failure, septic shock, and renal failure. Furthermore, in the same study, the authors estimated the years of life lost among these patients by using the Centers for Disease Control and Prevention life table and found that unplanned intubation, bleeding, and septic shock were associated with the greatest number of years of life lost (Table 9.1).

Outside the United States, Biccard et al. examined perioperative outcomes across 247 hospitals in 25 African countries and reported a 2.1% 7-day mortality rate, with 94% of deaths occurring after the day of surgery.[5] Importantly, this study included trauma and obstetric patients, with 57% of the entire cohort of 11,422 patients undergoing emergency operation and 11% having the comorbidity of HIV infection. Postoperative complications occurred in 18.2% of patients. Postoperative infection was the most common complication, occurring in 10.2% of all patients, and death occurred in 9.7% of patients experiencing postoperative infection.

Active, prospective perioperative mortality tracking and assessment are possible even in resource-constrained environments. For example, perioperative mortality was prospectively measured by a group of Kenyan anesthetists using an open-source electronic tool in a rural Kenyan tertiary hospital.[6] Seven-day perioperative mortality was 1.5%, ranging from 0.5% for cesarean section to 3.6% for emergency surgery. Their electronic tool also captured demographic, health status, and healthcare process data that highlight

TABLE 9.1 **Years of Life Lost Associated With Each Complication, per 1 Million Patients**

	IN STUDY POPULATION			PER MILLION SURGERIES		
COMPLICATION	**FEMALES**	**MALES**	**TOTAL**	**FEMALES**	**MALES**	**TOTAL**
Bleeding	3474	2378	5852	2895	1981	4876
Unplanned intubation	3110	3367	6477	2592	2806	5397

From Freundlich RE, Maile MD, Sferra JJ, et al. Complications associated with mortality in the National Surgical Quality Improvement Program Database. *Anesth Analg*. 2018;127:55-62.

the regional differences between healthcare delivery systems that complicate global comparisons. For example, the Kenyan patients tended to be younger and healthier as a group than the North American patients.

Another approach to comprehensive outcome and mortality assessment is structured sampling across a wide range of participating hospitals. Although this approach has advantages, the specific sampling approach and variable definitions may lead to a substantially different understanding of the same mortality data. In an observational sampling study of 7-day mortality in Europe, there was enormous heterogeneity around a high (mean 3.6%) mortality rate, even in places such as Great Britain.[7] This result provoked numerous reexaminations of the data and subsequently lower estimates.[8-13] In another prospective study in a similar patient population by the same research group,[14] the mortality was found to be lower. Assessing the differences is illustrative. In the prospective work, one of the study variables was postoperative oxygen saturation. The mortality in this prospective study was much lower, only about 1%. Of that mortality, 40% was in the intensive care unit (ICU). One offered explanation as to the driver of the difference is that in the prospective study, an investigator physically interacted with patients. The investigator recognized deteriorating patients and sent them to the ICU, where they either died or were rescued and recovered.

These categories of assessment have benefits and drawbacks. Prospectively recorded mortality data have the advantage of defined parameters and, in the case of the ACS NSQIP, a robust cross-validation program to ensure that data abstraction is consistent across centers. However, these programs are inherently vulnerable to bias because the measured end points are known to participating organizations, and there are strong incentives tied to the mortality statistic. When trying to estimate a rate for perioperative mortality, observational and retrospective studies appear to be the most trustworthy for finding an upper bound on the estimate. These types of studies are more “environmentally valid,” representing routine practice without unusual oversight or extra observation, but they require careful attention to definitions, case finding, and data curation. On the other hand, registries—including those with associated quality improvement efforts—offer the advantage of prospective definitions of perioperative mortality, active data collection, and dedicated data management infrastructure, but they probably represent optimistic estimates. The picture remains challenging, but the simple solution of paying more attention through leadership commitment to improving the quality of care via education and robust multidisciplinary systems of care supported by technology can produce real surgical quality improvements.

Although systems-level factors are rightly considered to improve surgical safety, it is important to remember that the individual surgeon’s technique still influences outcomes. For example, in a study[15] of 20 bariatric surgeons, there was a strong relationship between summary peer rating of technical skill (derived by expert review of blinded recordings of procedures) and risk-adjusted complication rates after laparoscopic gastric bypass. Each diamond in Fig. 9.1 represents 1 of 20 practicing bariatric surgeons. Technical skill was assigned on a 1-to-5 scale (5 being better) by blinded review performed by at least 10 other surgeons unaware of the identity of the operating surgeon. Complication rates were obtained from a prospective, externally audited clinical outcomes registry after adjustment for patient comorbidities. Surgical skill was predictive of the rate of surgical complications, nonsurgical (medical) complications, reoperations, readmissions, and emergency department (ED) visits, indicating that the technical skill of the surgeon is a potential driver of many of the system-level performance domains currently receiving much attention in the area of quality improvement. Although no parallel studies of anesthesiologist or intensivist skill have been conducted, it is likely that similar interprovider differences in skill and outcomes would be observed. Thus, the domain of provider-level contributions to harm and outcome remains largely unexplored and represents an area of unknown potential for improvement.

Perioperative safety issues put pressure not only on patients and healthcare workers but also on the economics of healthcare as

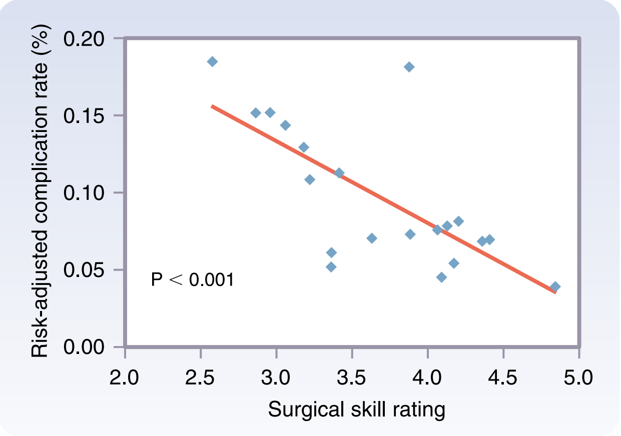

FIGURE 9.1 Relationship between summary peer rating of technical skill and risk-adjusted complication rates after laparoscopic gastric bypass. (From Birkmeyer JD, Finks JF, O'Reilly A, et al. Surgical skill and complication rates after bariatric surgery. *N Engl J Med.* 2013;369:1434-1442.)

a whole. In 2008, the cost of medical errors was estimated to be \$17.1 billion in the United States,[16] with other estimates reaching as high as \$29 billion.[17] Healthcare systems with worse quality outcomes have been shown to spend more money. A 2020 analysis of Centers for Medicare and Medicaid Services (CMS) data from 2194 hospitals demonstrated that hospitals that had higher rates of AEs were likely to have higher rates of expenditure for acute myocardial infarction (AMI), heart failure (HF), and pneumonia admissions. For every 1 percentage point in the AE rate, a hospital had an increased risk-standardized expenditure of \$103 for AMI, \$100 for HF, and \$152 for pneumonia admissions.[18] On the other side of the equation, interventions aimed at improving safety—such as checklists—have been noted to save significant money for healthcare systems.[19]

In 2000, the Institute of Medicine called for a national effort to reduce medical errors by 50% within 5 years; however, progress fell far short of that goal despite numerous private and public initiatives aimed at finding solutions, and it remains limited. Indeed, a 2014 study demonstrated an improvement in AE rates in patients hospitalized for AMI or HF but not for those admitted with pneumonia or conditions requiring surgery.[20]

Leape and colleagues[21] proposed that these efforts were not adequate because healthcare organizations had not undertaken the major cultural changes required to accomplish true and lasting improvements in performance. Leape and colleagues proposed that "health care entities must become 'high reliability organizations' that hold themselves accountable to consistently offer safe, effective patient centered care." These authors put forward the following five transforming concepts for adoption by healthcare organizations seeking such a transformative change in culture: (1) Transparency must be a practiced value in everything we do; (2) care must be delivered by multidisciplinary teams working in integrated care platforms; (3) patients must become full partners in all aspects of healthcare; (4) healthcare workers need to find joy and meaning in their work; and (5) medical education must be redesigned to prepare new physicians to function in this new environment.

With an eye to these principles, this chapter will discuss how to establish an environment that promotes safety, a number of specific safety concerns applicable to an intraoperative context, perioperative events that rely on a robust safety culture for management, and structures that can support safety culture.

ESTABLISHING AN ENVIRONMENT THAT PROMOTES SAFETY

The Joint Commission (TJC), a major accrediting body that aims to ensure quality standards across healthcare entities, published 11 tenets of a safety culture in 2017, as follows[22]:

1. Apply a transparent, nonpunitive approach to reporting and learning from adverse events, close calls, and unsafe conditions.
2. Use clear, just, and transparent risk-based processes for recognizing and distinguishing human errors and system errors from unsafe, blameworthy actions.
3. CEOs and all leaders adopt and model appropriate behaviors and champion efforts to eradicate intimidating behaviors.
4. Policies support safety culture and the reporting of adverse events, close calls, and unsafe conditions. The policies are enforced and communicated to all team members.
5. Recognize care team members who report adverse events and close calls, who identify unsafe conditions, or who have good suggestions for safety improvements. Share these "free lessons" with all team members (i.e., feedback loop).
6. Determine an organizational baseline measure on safety culture performance using a validated tool.
7. Analyze safety culture results from across the organization to find opportunities for quality and safety improvement.
8. Use information from safety assessments and/or surveys to develop and implement unit-based quality and safety improvement initiatives designed to improve the culture of safety.
9. Embed safety culture team training into quality improvement projects and organizational processes to strengthen safety systems.
10. Proactively assess system strengths and vulnerabilities and prioritize them for improvement.
11. Repeat organizational assessment of safety culture every 18 to 24 months to review progress and sustain improvement.

These recommendations find their way into clinical practice through institutional structures and tools that help promote safety as well as interpersonal factors that promote these principles.

A joint-governance structure in the perioperative system, wherein surgeons, anesthesiologists, nursing staff, advanced practice nurses, and other medical consultants are fully engaged in leadership, is vital to effective patient safety efforts. For example, at Vanderbilt University Medical Center, there are major service lines organized around the care of the surgical patient, and these are jointly led by the chairs of the departments of surgery and anesthesiology and by the nursing leaders of inpatient, outpatient, and perioperative care. The leadership of the perioperative enterprise is tripartite, with the chairs of surgery and anesthesiology and the associate chief nursing officer for perioperative services as coexecutives. These teams allow for transparency and fair adjudication of conflicts over scarce perioperative resources and promote behavioral modeling by example. They also demonstrate commitment to patient safety by investing departmental and institutional resources into the creation and operation of quality and safety organizations within their respective departments across the service line.

To be most effective, this joint governance must be accompanied by a multidisciplinary patient safety program. Such a program should operate in a blame-free culture with deference to expertise. Input to the program includes proactive scans for opportunities to improve systems but, importantly, features many routes for reporting nonroutine events, near misses, and critical events. Confidential web-based reporting systems provide a means for all members of the healthcare enterprise to provide such inputs, and they serve as a means of fulfilling TJC safety tenets 1 and 2. These programs allow for real-time quality improvement interventions and root-cause analyses that can produce small interventions and systems-level changes. At Vanderbilt, each of the major role groups has an appointed patient safety officer (PSO) who operates in concert with the perioperative chief quality officer. These individuals are chosen for their discretion and effectiveness at taking in and appropriately routing information about safety problems and for their ability to shepherd such investigations and process improvements through to completion. The quality management structure created in the Department of Anesthesiology at Vanderbilt can serve as one illustration of an effective and equitable system (Fig. 9.2). The surgical departments have an almost identical quality and safety organizational structure. The surgical and anesthesiology organizational structures are closely associated, and continuous communication links surveillance and intervention activities.

These institutional structures can be augmented by tools and standardized practices that promote safety—such as checklists and a universal protocol. Haynes and colleagues[23] demonstrated the impact of implementing a standardized surgical safety checklist on patient outcomes. In a study of more than 3700 surgical

Electronic whiteboard mediated time-out. Attention of personnel is focused on the display on which the time-out questions are being sequentially addressed. The display serves as a framing system for this important safety step. The view is from the anesthesiologist's position at the head of the bed, with *(from left to right)* the scrub technician, the circulator nurse, and the surgeon. The circulator's computer (visible to the lower right of the large display) shows the questions on the large display and captures the responses entered by the circulator. (From McEvoy MD, Wanderer JP, King AB, et al. A perioperative consult service results in reduction in cost and length of stay for colorectal surgical patients: evidence from a healthcare redesign project. *Perioper Med [Lond].* 2016;5:3.)

patients from eight major hospitals in eight cities worldwide, they found that implementing the checklist reduced complication rates from 11% to 7% and reduced postoperative death rate from 1.5% to 0.8%. Subsequently, de Vries et al. reported[24] that implementation of a comprehensive, multidisciplinary surgical safety checklist that included medications, marking of the operative site, and postoperative management plans in six hospitals in the Netherlands resulted in a significant decrease in complication rates and in-hospital mortality compared with a control group of five hospitals. When compared with a 3-month baseline period, the rates of total complications in surgical patients were reduced from 27.3 per 100 to 16.7 per 100. The proportion of patients with one or more complications decreased from 15.4% to 10.6%, and the inpatient mortality rate decreased from 1.5% to 0.8% in the surgical population among the study group of hospitals. Control hospitals did not experience a change in these outcomes over the same time intervals. Box 9.1 summarizes elements of surgical safety checklists.

In contrast to the aforementioned positive observational studies, Urbach and colleagues[25] reported the results of a group of 101 surgical hospitals in Ontario, Canada, using administrative health data to compare operative mortality, rates of surgical complications, and other 30-day postdischarge outcomes before and after adoption of a surgical safety checklist. They did not find a statistically significant difference in adjusted risk of death or surgical complications in the 3 months before and after implementation of a checklist. Although this did not seem to support the efficacy of checklists, the conclusions are limited by the short study interval (resulting in likely low levels of adoption and inadequate assessment of compliance and quality of practice using the checklist) and a low-acuity population, with 60.8% ambulatory cases and a high proportion of ophthalmology and musculoskeletal cases.

Preventing rare but devastating events is a separate, albeit still important, purpose of a surgical checklist. Nearly half of surgical “never events” resulting in indemnity payments in the United States result from “wrong surgeries”—encompassing a wrong procedure, wrong site, or surgery on the wrong person. Wrong surgery often results in significant injury or patient death and is devastating to the care team. Estimates of wrong-surgery incidence range from 1:112,994[26] to 1:5000[27] and may be increasing. Checklist application[23,28] has reduced the frequency of complications resulting in injury and death. TJC has made the implementation of the Universal Protocol for the prevention of wrong-site, wrong-patient, and wrong-procedure surgery, including the preprocedural time-out, an accreditation requirement.[29] The Universal Protocol includes the following elements: preprocedural verification, site marking, and final verification during the preprocedural time-out. Preprocedural verification includes verification of the appropriate history and physical examination in the medical record, the presence of a signed consent form, nursing assessment, and preanesthesia assessment (when applicable).

At Vanderbilt University Medical Center, a nonemergency patient cannot be transported to the operating room (OR) without completing these components of the preprocedural verification. This preprocedural verification continues in the OR, including verification that the necessary diagnostic laboratory, radiology, and other test results are present and properly displayed. The requirement for and presence of blood products, implants, devices, or special equipment are also confirmed in the preprocedural verification process. The time-out that occurs immediately before initiation of the procedure provides a final verification of the correct patient, correct site, and correct procedure. The time-out is most effective when it is standardized and conducted consistently in all procedural areas of the hospital; it should be conducted immediately before starting an invasive procedure or making the incision. It is initiated by a designated member of the procedural team and involves the immediate members of the procedural team. During the time-out, other activities are suspended so that team members may focus on active confirmation of the patient, site, and procedure. Any new team members should be introduced. At a minimum, the team members must agree on the correct patient identity, correct procedural site (with the site

BOX 9.1 Elements of the Surgical Safety Checklist

Sign In

Before induction of anesthesia, members of the team (at least the nurse and an anesthesia professional) state that the following have been done:

- The patient has verified their identity, surgical site and procedure, and consent.
- The surgical site is marked, or site marking is not applicable.
- The pulse oximeter is on the patient and functioning.
- All members of the team are aware of whether the patient has a known allergy.
- The patient’s airway and risk of aspiration have been evaluated, and appropriate equipment and assistance are available.
- If there is a risk of blood loss of at least 500 mL (or 7 mL/kg body weight in children), appropriate access and fluids are available.

Time-Out

Before skin incision, the entire team (nurses, surgeons, anesthesia professionals, and any others participating in the care of the patient) or specific members state aloud the following:

- Team confirms that all team members have been introduced by name and role.
- Team confirms the patient’s identity, surgical site, and procedure.
- Team reviews the anticipated critical events.
  - Surgeon reviews critical and unexpected steps, operative duration, and anticipated blood loss.
  - Anesthesia professionals review concerns specific to patient.
  - Nurses review confirmation of sterility, equipment availability, and other concerns.
- Team confirms that prophylactic antibiotics have been administered ≤60 minutes before incision is made or that antibiotics are not indicated.
- Team confirms that all essential imaging results for correct patient are displayed in operating room.

Sign Out

Before the patient leaves the operating room, the following are done:

- Nurse reviews the following aloud with the team:
  - Name of procedure, as recorded
  - That needle, sponge, and instrument counts are complete (or not applicable)
  - That specimen (if any) is correctly labeled, including patient’s name
  - Whether there are any issues with equipment that need to be addressed
- The surgeon, nurse, and anesthesia professional review aloud the key concerns for the recovery and care of the patient.

marking verified when laterality or level is a concern), and correct procedure to be done. Finally, completion of the time-out should be documented for the patient's medical record.

Checklists must be performed reliably to be effective, which requires the care team to achieve optimal performance consistently. This is a potential vulnerability. To create a technologic backstop to team performance, Vanderbilt used automated process monitoring and process control as well as forced function concepts to implement an electronic time-out checklist to reduce the wrong-surgery rate.[30] Vanderbilt created an electronic preprocedural briefing and time-out checklist mediated via the intraoperative nursing documentation module of its OR documentation system. Checklist questions were sequentially displayed to the entire care team on a large in-room monitor (Fig. 9.3), interposed as a required documentation step between the "patient-in-OR" and "incision" events. During the studied interval between 2010 and 2015, no wrong surgeries were detected, compared with two in the 6 years before deployment. Bayesian analysis suggested an 84% probability that the wrong-surgery rate was lower after process implementation, but given the low overall rates of these events, there remains significant statistical uncertainty as to the efficacy of the intervention and whether future events with similarly rare causes may be prevented by checklists and time-outs.[30]

In the OR environment, interpersonal factors can have a sizeable effect on a safety-focused culture. Communication failures frequently contribute to AEs, in addition to inefficiencies and resource waste.[31,32] Failures encompass issues with timing of communication, content of information (completeness and/or accuracy), lack of resolution of issues, and exclusion of key stakeholders.[32] Although these issues abound and can be difficult to address, a review of the literature related to intraoperative communication[33] identified team integration, flattened hierarchies, and structure/standardization as factors that supported effective communication. It also advocated for use of closed-loop communication as well as checklists, safety briefings, and specific training for teamwork in service of this outcome. Specific training using principles from aviation safety has been shown to increase the efficacy of communication in the OR as well.[34] These tools—including their use in simulation-based practice[35]—become additionally important in situations at high risk for communication breakdown,[36] such as emergencies, intraoperative complications, and procedures that involve multiple surgical and anesthesiology teams.

A specific type of interaction that may have significant safety implications is that of the surgeon-anesthesiologist dyad. A 2018 article simultaneously published in the *Journal of the American College of Surgeons*[37] and *Anesthesiology*[38] by patient safety expert Dr. Jeffrey Cooper posited the requisite nature of effective teamwork between a surgeon and anesthesiologist in producing high-quality care. He drew several conclusions based on discussions with both surgeons and anesthesiologists. The article suggests that when teamwork exists and is functional, it serves the interest of the patient and creates a more favorable environment for all parties. The converse is also frequently true, which can pose safety concerns. Cooper also describes frequently noted presupposed beliefs about the other group and their motivations in a given interaction, which are occasionally not necessarily driven by the patient's best interests. This article, although thought provoking, did not offer any empirical evidence to support its central thesis. Subsequent research, however, has suggested the veracity of these arguments. Hallet et al.[39] showed, in a population-based study of 7893 patients undergoing complex gastrointestinal cancer surgery, that increasing familiarity of the surgeon-anesthesiologist team improved short-term outcomes. This was quantified as a 5% decrease in 90-day major morbidity each time a unique pair worked together.

At Vanderbilt, the identified importance of team-based interactions centered on collegiality, effective communication, and mutual respect has resulted in the development of a Co-Worker Observation Reporting System (CORS). This is an anonymized reporting database for suboptimal professional behaviors that is backed by strong leadership engagement and interaction and provides individuals with access to institutional wellness support structures. With use of this system, three-quarters of identified providers avoided recidivistic interactions after an initial structured intervention.[40] Based on the type, frequency, and pattern of events or concerns, an intervention algorithm is applied. Initially, a nonjudgmental, nondirective conversation occurs between a "concerned professional" and a colleague, regardless of hierarchy.

If repeated nonprofessional behaviors manifest, institutional structures exist to provide opportunities to access a variety of resources to support physician and provider wellness, inclusive of counseling support, substance abuse intervention, and psychological-cognitive evaluation.

A similar system exists for addressing patient complaints about provider interactions. This system has been associated with a substantial improvement in patient satisfaction and a significant reduction in malpractice-related costs. The patient reporting system has also recently been identified as signaling the potential for provider-centric suboptimal outcomes.[41] Team-based satisfaction has also been enhanced and has resulted in microenvironment team satisfaction improvements that have had reciprocal effects on patient and family approbation of care. This system has been expanded more recently to include concerns of other members of the team about providers that may have adverse consequences for healthcare team interactions and care outcomes. The team-based concerns have identified numerous areas for improvement in provider behaviors and have increased within-team functionality.

WHAT MAJOR SPECIFIC SAFETY CONCERNS EXIST IN AN INTRAOPERATIVE CONTEXT?

Sterility and Environmental Issues

The importance of sterility and hygiene has been recognized since Semmelweis first noted the beneficial impact of hand hygiene on mortality rates among patients undergoing delivery by midwives.[42] This understanding continued to evolve through William Stewart Halsted's commissioning of the Goodyear Rubber Company to develop rubber gloves that he mandated all members of his surgical team wear throughout each operation in an effort to control and prevent infection.[43] Despite over 100 years of progress and development of sterile technique (loosely defined as a system of practice aimed at eliminating microbial contamination), sterility remains a fundamental area of ongoing safety concerns. The maintenance of sterile technique throughout an operation is highly regimented, with guidelines existing for everything from how a surgeon is gowned to how a field is draped and instruments are passed.[44,45] As with many aspects of healthcare safety, it unfortunately takes only one mistake within the process of establishing sterile technique to introduce contamination and potentially result in a surgical site infection (SSI). Breaks in sterility are grouped into types 1 through 4 based on the time of recognition, with type 1 breaks being caught immediately and type 4 breaks not being recognized until after a patient has left the OR.[46]

In an effort to promote sterility, the surgical environment and built infrastructure of the operating space are highly regulated by both medical and government agencies. These regulations are critical to promote a safe operating environment and reduce the risk of contamination from both the outside environment and the OR environment between cases. Measures to ensure the sterility of the OR include the use of positive air pressure to direct airflow and high-efficiency particulate air filters to reduce the burden of airborne contaminants.[47] Beyond simple sterility concerns, the physical state of the OR also directly affects patient safety; for example, it has been demonstrated that the maintenance of patient normothermia is associated with lower rates of SSI.[48] Similarly, overall cleanliness of the OR and the presence of surface dust, clutter, and dirty personal effects worn by personnel or placed in the OR all represent (at the least) reasons for concern about their potential risks to maintaining sterility in the surgical field.

Surgical Management Concerns

The care and safety of the patient in the OR start long before the patient enters the sterile space. Careful patient selection ensures that patients' multiple risk factors, comorbidities, and potentially optimizable conditions are taken into account when offering surgical intervention and selecting the most appropriate surgical operation.[49] Once a patient has been thoroughly evaluated, their risk profile determined, and the safest operation for them selected, they need to give their informed consent to be operated on. This process represents an important legal, ethical, and professional responsibility of physicians, whereby competent patients are adequately informed and not coerced regarding the risks, benefits, and alternatives of an operation before providing their voluntary consent.[50] On arrival to the OR, this consent should be confirmed with the patient and verified by all members of the operating team.

The critical surgical phases of care can be roughly broken down into three major aspects of care: entry, resection or repair, and closure. Entry, or the "opening" of a case, is usually a more predictable portion of the operation, particularly in elective cases. The selection of incision and modality (i.e., open vs. laparoscopic) can be tailored to a patient's pathology and comorbidities. The selection of an inappropriate entry, such as attempting a laparoscopic entry in a frozen abdomen, can be expected to lead to increased rates of surgical complications. Even in straightforward operations with anticipated favorable anatomy, the opening to a case requires strict attention to detail and the same meticulous care as all other phases of the operation. Failure to properly locate an incision can lead to difficulties with dissection, resection, or reconstruction later in the case. An improperly sized incision can likewise affect healing or cosmesis.

The critical portion or portions of the case vary widely depending on the patient, pathology, and procedure but can be broadly thought of as the repair, resection, or reconstruction of a given patient's disease. Although this variety means that the concrete definition of a *critical portion* remains somewhat amorphous, it is generally thought that this portion of the case presents the most serious challenge to the surgeon and that mistakes made here are of the greatest consequence to a patient.[51] Here, the safety concerns are obvious: Mistakes or missteps increase the difficulty of the case and may even alter exactly what operation can be performed. This portion of the case provides the most opportunity for preparation and planning. Inexperienced surgeons or those in an operation they perform infrequently should arrange for backup or surgical support from colleagues as needed. Lastly, because this portion of the case is often the least standardized, close communication with other surgical team members is paramount and necessary for anticipating variances and the need for other surgical adjuncts.

Like the opening of a case, closure often occurs in a standard format that has the potential to lead to complacency. Strict attention to hemostasis and instrument/sponge counts is necessary before any closing stitch is called for. This portion of a case likewise offers an opportunity to confirm specimen labeling or mesh counts. As with all portions of the case, strict adherence to best practices and surgical technique are necessary to avoid the development of complications such as retained objects, hernia, or SSI.[52]

Anesthesia Concerns

Two of the most critical portions of an anesthetic are induction and emergence. During these periods, the patient is transitioning from an awake state with their baseline airway and hemodynamic reflexes to the anesthetized state in which they lack these protective functions. In general anesthesia cases, immediately after the anesthesia provider administers induction drugs, the patient will become apneic. Drug-induced apnea will likely lead to brain death if not reversed. Establishing airway patency and/or control depending on the patient and procedural needs is the paramount next step in the safe induction of general anesthesia. Successful airway control is the rule, but it is not assured. Awareness and vigilance by the surgical team and OR staff during this period promote patient safety because the final step in the (rare) cannot ventilate–cannot intubate scenario is an unplanned cricothyroidotomy on a hypoxic and rapidly deteriorating patient. The rarity of cannot ventilate–cannot intubate induction events, coupled with the extreme temporal pressure, virtually guarantees a chaotic surgical airway and poor outcome. The surgical team plays a leadership role in the OR by setting a tone that allows for focus on this critical task, including paying specific attention to the progress of induction. Paradoxically, the combination of better drugs, better training, alternative airway adjunct tools, and better airway management techniques have decreased the incidence of challenging inductions, potentially increasing complacency and diminishing both experience and psychological preparation for decisive surgical airway management as a last resort. Other anesthetic techniques have different but similar profiles of rare but severe failure modes. For example, regional anesthetic techniques may devolve into local anesthetic systemic toxicity (cardiovascular collapse) or total spinal anesthesia, both of which will abruptly pull the surgical team into an unfamiliar resuscitation.

During emergence, if the airway management strategy does not include an endotracheal tube, the patient is at risk of sudden closure of the vocal cords, or laryngospasm, as they pass through the excitement phase. This can also occur if an endotracheal tube is removed before the patient is fully awake because brainstem reflexes such as a cough and gag return before the primitive laryngospasm reflex being extinguished. Laryngospasm can result in severe hypoxemia and, in severe cases, bradycardic arrest. Other safety issues that can arise on emergence are aspiration and agitated delirium. Surgeons can further patient safety in each of these conditions by helping to manage the room and directing resources to the anesthesia team handling the problem.

Hemodynamic management can be a complex part of anesthetic maintenance, depending on patient and procedural factors. Patients with significant cardiac disease can pose challenges and may require invasive monitoring in order to ensure adequate myocardial perfusion. Timing of monitor placement is generally determined by whether the anesthesiologist assesses that anesthetic induction itself will pose a large enough risk of instability that beat-to-beat hemodynamic monitoring with an arterial pressure monitor—or in some cases, a pulmonary artery catheter—is necessary before anesthetic induction. Noninvasive cardiac output monitors can be employed at some institutions to help with evaluation and medication titration. Most anesthetic drugs are vasodilators, so a small vasopressor requirement—either in bolus doses or as an infusion—can be present even in straightforward cases. When a patient becomes acutely hemodynamically unstable, anesthesiologists may employ higher doses or more potent agents that are selected based on the hypothesized pathophysiology of instability. Communication between the anesthesia and surgical teams is key to patient safety in these instances because contributing factors and appropriate solutions exist on both sides of the curtain.

The anesthesia team's ability to resuscitate a patient in the event of massive hemorrhage or significant hemodynamic instability is significantly influenced by adequate monitoring and vascular access. It becomes more technically challenging to obtain this access during crisis situations because patient positioning may make limb access challenging, other management concerns may acutely compete for the anesthesia provider's immediate attention, and vasculature becomes more difficult to access during shock states. Accordingly, many anesthesia teams will err on the side of more or larger access.

The intraoperative anesthesia environment is perhaps unique in a modern hospital system in that medications are obtained, prepared, and administered by a lone provider. This introduces the possibility of error because many of the safety checks in place in other parts of the hospital include personnel redundancy. A review of the literature[53] on medication errors in the OR outlines a number of standards that have been operationalized by anesthesia teams. This includes medication labeling (color-coded by drug class; including drug name, date, and concentration), standardization of drug trays across service locations, use of bar codes and scanners for confirmation of drug vials, the practice of double-checking vials/syringes before administration, the availability of prefilled syringes prepared by pharmacy when possible, and a blame-free incident- or error-reporting system to track and escalate information about events as they occur.

PERIOPERATIVE EVENTS THAT RELY ON SAFETY CULTURE FOR IDENTIFICATION AND MANAGEMENT

Wrong-patient, wrong-site, and wrong-procedure surgeries are considered "never events" by the National Quality Forum and share common risk factors and prevention strategies. *Wrong-patient surgery* refers to performing a correct procedure on the incorrect patient (e.g., performing an appendectomy on the wrong patient when two patients share a similar last name), whereas wrong-site surgery most often involves laterality errors (e.g., performing a right nephrectomy rather than left), and wrong-procedure surgeries involve performing the incorrect procedure on the correct patient (e.g., performing a hysterectomy and oophorectomy on a patient who should only have received a hysterectomy). Risk factors for these events (including multiple surgeons in the same operation, time pressure, emergency surgery, and others) have been previously described by TJC and others, and in 2003, the Universal Protocol was introduced in an effort to mitigate these risks.[54] The Universal Protocol consists of three key steps: a preprocedure verification (confirming the correct procedure, for the correct patient, at the correct site), marking the procedure site, and performing a time-out that includes all members of the procedure team.[55] Despite these efforts, wrong-site surgeries continue to occur, although the incidence is difficult to estimate. A 2015 systematic review found that incidence estimates for wrong-site surgery in the United States were highly variable, with a median incidence of 0.09 per 10,000 surgical procedures.[56] Evidence on the impact of Universal Protocol implementation is mixed, with many studies demonstrating a marked decrease in wrong-site surgeries and others suggesting protocol implementation increases complexity without improving outcomes.[24,26,57,58] Recent analyses using claims data have found that the services most commonly involved in wrong-site surgery include orthopedics, neurosurgery, and urology, with spine surgery being particularly high risk. The top contributing factors in a 2023 systematic review were failure to follow policy/protocol (83.8%) and failure to review medical records (41.2%).[59] Wrong-site surgery is a rare but potentially devastating event, and it is critical that all members of the healthcare team are engaged in efforts to prevent these errors from occurring. As described earlier, team member engagement and the creation and use of presurgical checklists are not sufficient to reliably eliminate such "never events." Even relentless execution of the checklists themselves and the meta-checklist activities, such as real-time oversight audits of presurgical checklist application, can only reduce the rate of wrong surgery. Nevertheless, a high-reliability perioperative surgical organization requires this effort.

Retained foreign bodies (or retained surgical items) occur when a surgical instrument or sponge is inadvertently left behind at the conclusion of a case. These objects continue to be a source of significant patient morbidity as well as medical and liability costs and may occur in as many as 1 in 700 high-risk surgical procedures.[60,61] These events are increasingly seen not as individual errors on the part of surgeons or surgical teams but rather as human error made worse by poor communication and inadequate policies indicative of a lack of safety culture. Carmack et al. demonstrated the effect of implementing a multi-institutional evidence-based best-practice bundle that focused not just on the potential technologic solutions (e.g., visual counters or imaging) but also, just as importantly, culture and process improvements such as surgical stops, debriefs, and improvements in reporting. These interventions yielded impressive results and demonstrated an almost 20% increase in the time between events involving retained surgical items.[62]

Fires in the OR continue to pose serious risks to both patients and providers alike. Fires occur when the fire triad—namely, fuel, oxygen, and an ignition source (such as a laser or hot laparoscope)—combine, accounting for over 600 fires and several fire-related deaths annually. In the vast majority of these cases, it is the electrosurgical cautery that provides the ignition, owing in part to its almost universal use in modern ORs.[63] Despite the fact that ignition in surgical fires most commonly comes from the Bovie pencil, little has been done to update its design. However, important work is taking place regarding educating surgeons and other members of the OR team about the risk of OR fires and the safe usage of energy sources. The Fundamental Use of Surgical Energy (FUSE) course promulgated by the Society of American Gastrointestinal and Endoscopic Surgeons (SAGES) aims to educate team members on elements of fire prevention and techniques to disrupt the fire triad as well as strategies for communication as an OR team when high-risk situations are at hand.[64]

Tissue/specimen handling errors most often involve tissue loss (e.g., accidental failure to place tissue specimen into the appropriate container) or issues with specimen labeling. Appropriate specimen handling and accurate labeling are major patient safety priorities of both TJC and the College of American Pathologists. Surgical specimen identification errors may include a lack of labeling, empty containers, or mislabeling (including incorrect patient, incorrect laterality, or incorrect tissue site).[65] These types of errors can lead to significant patient harm, including delay in diagnosis, an incorrect patient diagnosis, and wrong-side treatment.[66] Estimates of surgical specimen identification errors are variable, but a 2007 study estimated the incidence to be approximately 4.3 per 1000 surgical specimens.[65] **Increasingly, newer technologies such as bar coding and radio frequency chip methods are being employed by surgical pathologists to reduce the frequency of errors, and safe specimen handling is now regarded as an important patient safety measure.**[67]

Surgical site infection is defined as an infection at or near an incision that occurs within 30 days of surgery or within 90 days if a prosthetic is implanted. According to a 2023 *Journal of the American Medical Association* review about SSIs, this problem affects between 0.5% and 3% of patients having a surgical procedure and can increase hospital length of stay by 7 to 11 days.[68] The review found six strategies for SSI prevention that are supported by the literature: (1) avoidance of razors for hair removal, opting for clippers instead; (2) decolonization with intranasal antistaphylococcal agents and antistaphylococcal skin cleansers for high-risk procedures; (3) use of chlorhexidine gluconate and alcohol-based skin preparation; (4) maintenance of normothermia with active warming to keep a core temperature >36°C; (5) perioperative glycemic control (maintain glucose <150 mg/dL); (6) and negative-pressure wound therapy. Guidelines also support appropriate preoperative antibiotic dose, timing, and choice based on procedure. Electronic medical record (EMR) systems can provide automated decision support and reminders for several of these steps to ensure adherence to guidelines with good effect. For example, automated systems have been shown to be effective in reminding providers to adhere to perioperative insulin guidelines, thus reducing SSIs in patients with diabetes,[69] and to administer perioperative antibiotics at an appropriate time.[70]

Intraoperative adverse events are defined as injuries suffered by patients as a result of medical or surgical management that occurs during an operation or procedure. Among the already high burden of AEs occurring in any phase of medical care, intraoperative AEs are among the most common, second only to adverse medication reactions.[3] This burden is reflected in malpractice data, which demonstrate that over three-fourths of claims made against surgeons are related to intraoperative events.[71] Beyond the administrative and medical-legal impacts, intraoperative AEs are known drivers of surgical morbidity and mortality.[72] For years, the classification and study of intraoperative AEs lagged behind the characterization of overall AEs largely because intraoperative data were hard to abstract compared with data from a patient's overall clinical stay. This has been remedied in part by the development of severity classification scales for intraoperative events.[73] An example of one of these tools is the ClassIntra classification system. This scale grades deviation from the ideal intraoperative course from I to V, with increasing grade corresponding to increased severity. It is important to note that the scale relies on injury rather than event. For example, bleeding in a grade I event is classified as above average and self-limited, whereas a grade IV bleed is life threatening and would require massive transfusion and ICU resuscitation.[74] Risk factors for intraoperative AEs are varied. Patient-related factors include advanced age, increasing functional dependency, and severe comorbidities (e.g., metastatic cancer).[75] Surgical complexity certainly increases the risk of AEs, with increased relative value units (used as a surrogate for increased complexity) associated with higher rates of AEs.[76] Lastly, surgical ability, in terms of both direct technical ability and human factors skills such as fatigue management and communication, has been demonstrated in several studies to be associated with intraoperative AE rates.[77]

The current generation of surgery may come to be defined in part by the rapid advancement and adoption of advanced surgical technologies. Increasingly, pathology that previously required open operations is being treated with minimally invasive, robotic-assisted, and even endoscopic or other procedural means, with equivalent outcomes. With this increased reliance on technology comes a new potential source of patient harm if these devices malfunction. Some form of equipment failure is relatively common, occurring in as many as 38% of cases involving adjunctive minimally invasive equipment in some studies.[78] Importantly, human error still plays a significant role in as many as half of equipment failures.[78] As technologic complexity grows, surgeons are increasingly being asked to perform the role of biomedical engineers to troubleshoot and correct problems with equipment, particularly when operating outside of normal hours, when on-site technical support may not be available. When examining robotic platforms, studies have demonstrated that equipment malfunction can result in injury to patients as often as 15% of the time.[79] Similarly, with the advent of minimally invasive techniques, the use of mechanical or automatic staplers has become more common, again introducing a new potential source of error. A full two-thirds of academic minimally invasive surgeons have encountered stapler misfires, with the problem noted to extend across different models and manufacturers. There have been over 100 deaths attributed to stapler misfires, but the true rate of harm is likely higher because silent misfires resulting in delayed leaks may be blamed on other technical or patient factors.[80,81]

Emergency and trauma cases deserve special mention here because their time-dependent and nonelective nature requires preexisting systems of care to be in place to provide optimal patient care. The resuscitation of a patient who requires hemorrhage control is a complex event requiring coordination of the individual members of the surgical and anesthetic teams as well as the blood bank to provide blood products in prescribed ratios[82] because these actions are key to achieving hemostasis.[83] The timing of intubation or surgical airway remains an important area of study, with recent data supporting waiting to secure the airway of a hemorrhaging patient until the OR as opposed to securing the airway in the ED. This is supported by a recent study of almost 10,000 trauma patients in which the almost 20% of patients who underwent intubation in the ED had higher rates of mortality, delay, and complication[84] compared with those who were intubated in the OR.

Overlapping surgery presents a unique challenge to a healthcare system trying to harmoniously balance allocation, efficiency, and safety. *Concurrent* or *simultaneous surgery* provides the greatest systems-based challenge because this refers to procedures where critical portions are occurring in more than one case simultaneously. It is generally accepted that this form of surgery is always inappropriate because it leaves no safety margin in place should simultaneous emergencies occur that require the attention of the operating surgeon. As opposed to concurrent surgery, *overlapping* or *sequenced surgery* refers to the operating surgeon participating in another operation upon completion of the critical portions of a case. This has been studied extensively, although not with a randomized control trial, and to date, no demonstration of differences among patient safety measures has been found.[85]

Intraoperative deaths (IODs) are a rare but devastating class of safety events. There is a paucity of data regarding these events, but an analysis of 41 IODs at a large academic center attempted to classify them in order to identify contributing factors.[86] The larger phenotypes designated were trauma, nontrauma emergency, and elective surgery, with subphenotypes for arrests related to medical and vascular injury/bleeding. The researchers found that 42% of trauma patients required cardiopulmonary resuscitation before incision, 33% required resuscitative thoracotomy, and transient return of spontaneous circulation occurred in 30% of patients. Aortic aneurysm rupture comprised about half of all nontrauma emergencies, and the use of blood products was substantial (median 2694 mL). In medical arrests among elective surgery patients, preoperative evaluation did not include cardiac consultation in 62% of cases and did not include a stress test in 87% of cases. Elective surgery patients who died as a result of vascular injury/bleeding notably had only one peripheral IV line in 83% of cases, prompting escalation in monitoring and access and need for surgical backup.

WHAT STRUCTURES CAN SUPPORT SAFETY CULTURE?

A previous section touched on the multidisciplinary local organizational structure to promote safety culture, using Vanderbilt as an example. As discussed, the structure allows for blame-free reporting and systematic review of AEs, with the intent of identifying root causes and developing strong countermeasures to prevent recurrences. The culture-of-improvement orientation allows for academic review of safety events as learning opportunities. The collegial culture also fosters the creation of policies and protocols (such as those geared toward Enhanced Recovery After Surgery [ERAS]) that can improve outcomes. With regard to harm events, the PSO from each department can refer issues to the multidisciplinary Quality, Morbidity, Mortality Improvement (QMMI) Committee to deal with system-of-care problems amenable to structural, procedural, and technical solutions or to the Peer Review Committee to deal with events related more to individual performance, knowledge, and decision-making, or both. The departmental PSO collaborates with PSOs from other professional departments and from perioperative services, all under the umbrella of the multidisciplinary QMMI Committee, which is cochaired by the surgery and anesthesiology PSOs.

Projects referred to the QMMI Committee have included refreshing protocols for cardiac implantable electronic device management, multidisciplinary development of policies and procedures for management of surgical patients receiving dual antiplatelet therapy for maintenance of drug-eluting intracoronary stents, optimization of perioperative assessment and management of the patient with sleep apnea, and adoption of postsurgical structured debriefs. These are public projects. Alternatively, most of the work of the Peer Review Committee is confidential and protected from discovery by legal statute. The Peer Review Committee comprises individual clinicians selected for their clinical acumen, probity, and discretion.

The departmental PSO maintains a confidential database of reports, analyses, projects, and dispositions of QMMI projects as well as Peer Review Committee referrals. Because of the sensitive nature of the work and the need to preserve a safe environment for reporting, the entire safety reporting and peer-review process is firewalled from operational leadership (i.e., the people who make decisions about OR access, team assignments, salaries) unless there is a QMMI Committee recommendation or a Peer Review Committee recommendation for executive action (see Fig. 9.2).

Another example of multidisciplinary efforts to optimize surgical and health outcomes is ERAS programs. Thoughtful ERAS implementation can simultaneously reduce length of stay and complications[87,88] while also favorably affecting topical considerations such as postoperative opioid consumption and postoperative nausea and vomiting.[89] It is important to keep the focus on application of scientifically sound tactics to speed and improve the recuperation from surgery rather than focusing on surrogate end points such as cost or length of stay. A well-implemented patient-centered ERAS program will produce better patient outcomes in which the economic outcomes become incidental, although they are virtually assured.

Despite more than 20 years since the formal description of ERAS pathways, there is much to be discovered, and there are many opportunities for broader implementation. The original ERAS protocol focused on colorectal surgery, and it is unclear whether many of the tactics developed for this patient population are relevant or translatable to other surgical patient populations.[90] The focus on length of stay as an outcome in the ERAS literature and the reflexive transfer of ERAS tactics between surgical domains without reassessment of their benefit/risk profile have led the originator to caution that ERAS interventions should be scientifically based and holistically studied rather than focused on operational or financial outcomes.[91] Ideally, ERAS protocols should be developed and implemented using formal quality improvement methods, including rigorous effectiveness and risk testing of new techniques or tactics transferred between patient populations. The implemented protocols should be parsimonious, including only those tactics yielding the best benefit-to-risk ratios, and they should be presented in easy-to-remember formats, as shown in Fig. 9.2. At Vanderbilt, ERAS protocols are periodically subjected to formal literature review to update evidence and revise the protocols, and the protocols themselves are accessible via direct link from the sidebar of the electronic health record (EHR). The Perioperative Quality Initiative[92] is an international consortium focused on early surgical recovery that produces readily accessible guidelines and evidence syntheses focused on ERAS and early recovery protocols that are all subject to revision as the quality of evidence improves over time.

On a higher level, healthcare systems can be restructured with quality outcomes in mind. Implementation of a surgical continuum of care (SCoC) model and continuum of care (CoC) for medical/surgical populations within the Geisinger Health Systems hospitals resulted in improvements in mortality rates, reductions in length of stay, and cost savings.[93] These models of care were implemented based on the hypothesis "that a surgical patient with physiological deterioration during the hospital course would have had a variable period of occult deterioration before the 'critical event' that results in activation of code team for cardiopulmonary arrest." The SCoC and CoC models involved redesign of care delivery to include hospitalist comanagement of adult surgical patients in the SCoC model and the hospital-wide adult population in the CoC model. Central elements of the redesigned models of care included multidisciplinary floor-based team building, unit cohort-based placement of patients according to degree of physiologic derangement and anticipated risk of deterioration, the creation of a safety-net unit called the Progressive Care Unit, and intensivist/hospitalist staffing of the Progressive Care Unit. In addition, the care teams organized acuity-stratified rounding on higher-risk patients at periodic intervals and implemented a real-time communication technology system. In a study of more than 100,000 admissions, these interventions resulted in a decrease in the risk-adjusted mortality index from 1.16 before intervention to 0.77 by 6 months after intervention with an unchanged case-mix index. The interventions also significantly decreased length of stay and resulted in cost savings in the high-risk and high-acuity populations of patients.

Vanderbilt has a dedicated group of nurse practitioners with a supervising critical care physician that responds to all rapid response activations in the hospital, known as the *critical care outreach team* (CCOT). This team structure has led to an increase in rapid response activations by concerned nursing staff as a result of familiarity with the team and a reduction in ICU transfers as a result of earlier intervention when patients showed signs of decompensation[94]; these changes occurred without increasing mortality and while improving billing for the hospital.[95]

When evaluating the results and impact of quality improvements resulting from mandates or public reporting, it is important to consider the source of the data being reported and the incentives of all the reporting individuals. Farmer and colleagues[96] drew attention to the precipitous decrease in rates of central line–associated bloodstream infections (CLABSIs) in the course of one quarter after the CMS terminated reimbursement for CLABSI treatment (Fig. 9.4). These CLABSI rates were derived from a national sample of administrative data used for billing, which heretofore had been assumed to accurately reflect the care provided. However, Lee and associates,[97] using an outcomes data source (outcomes data reported by institutions to a national quality database), saw essentially no immediate change in CLABSI rates around the period when CMS stopped reimbursements (see Fig. 9.4B). Similarly, they saw no change in catheter-associated urinary tract infections or ventilator-associated pneumonia around the time of cessation of reimbursement by CMS for these complications, whereas Farmer and colleagues detected a precipitous decrease in administrative coding for another surgical complication, retained foreign body, exactly concomitant with the cessation of reimbursement. Continuous effort to improve surgical outcomes is consistent with the ethos of the surgeon and the right thing to do. However, in the current reimbursement environment, there can be perverse incentives that may limit the impact of quality improvement initiatives. For example, when conducting a complete financial margin analysis of initiatives to reduce complications, a study demonstrated that successful programs may result in a negative cash flow to a hospital unless the hospital's surgical volume is growing sufficiently to fill beds vacated by patients who avoid complications.[98] This finding drives home the importance of sharing the financial benefits of successful quality improvement efforts between the providers and the payers.

With regard to systems-level interventions to improve safety, an understanding of how pieces of the system interrelate is vital before change can be attempted. *Perioperative systems design* describes a rational approach to managing the convergent flow of patients having procedures from disparate physical and temporal starting points (frequently home), through the OR, and then to such a place and time (e.g., home or hospital bed) where future events pertaining to the patient have no further impact on OR operations.[99] This process for an individual patient can be envisioned as a set of interdependent activities beginning with the decision to perform an operation and ending when the patient definitively recovers from surgery. The risk of disruption is briefly illustrated in Fig. 9.3, which approximates the steps required to bring a patient through an operation as well as common roadblocks. At each point, physical infrastructure and work processes affect patient progress, quality, safety, and system efficiency and are vulnerable to perturbations. Problems in a single patient's care can ripple across the OR suite or health system as well. Although the perioperative process is commonly conceptualized as a consistent system, workflow analyses reveal that even "defined" workflows have so many exceptions as to be essentially chaotic.[100] Frequently, improvements in one aspect of a perioperative system design highlight fragilities elsewhere. For example, improving OR throughput often unmasks limits to postanesthesia care unit (PACU) capacity.[101] In practice, many steps in the perioperative process are completely dependent on the successful completion of the preceding steps. This tight linkage implies that perioperative systems must be considered globally when making changes to one

FIGURE 9.4 (A–B) Timeline for intraoperative period. *ICU,* Intensive care unit; *OR,* operating room; *PACU,* postanesthesia care unit. (From Sandberg WS, Ganous TJ, Steiner C. Setting a research agenda for perioperative systems design. *Semin Laparosc Surg.* 2003;10:57-70.)

facet. Any proposed quality, safety, or efficiency improvement effort should be evaluated in terms of its likely and potential positive and negative impacts on the overall perioperative process.

Technologic tools are a promising avenue for creating reliability in quality-focused systems and processes. EMR systems can allow for assessment of incidence of safety events across single[102,103] and multiple institutions[104] and hold the potential for identifying controllable risk factors for poor perioperative outcomes. At an individual patient level, the EMR can assist with monitoring patient progress through the therapeutic encounter and comparing progress with the desired plan. Although current technology is insufficient to fully achieve this idea for a perioperative encounter, subtasks may be amenable to electronic process monitoring and process control.[105,106] For example, important perioperative documentation tasks, process steps such as timely administration of perioperative antibiotics, and improvements in intraoperative monitoring have been achieved using systems with computerized ongoing continuous monitoring of the perioperative process and automatic reminders sent directly to the bedside provider when process exceptions are detected.[70,107,108] Technology can also move electronic decision support even closer to the patient. For example, investigators at Dartmouth[109] were able to reduce the rate of unplanned ICU transfers by the simple expedient of placing a pulse oximeter connected to a system that propagated SpO_2 alarms from the patient's room to the nurse on all patients in the monitored units. The system was so successful that Dartmouth implemented continuous pulse oximetry for all inpatients.

Although these automatic systems hold promise, usability and implementation success rely on attention to workflow design, as previously alluded to. Fig. 9.4 provides a simple example of a system intended to ensure that all patients entering the recovery room have a set of postoperative orders by the time handover is complete. In the top workflow, the system is set up to notify the physician to write orders if no PACU orders are found in the computerized physician order entry (CPOE) system by the time the patient enters the PACU. Consequently, the notification, if it fires, technically gives its notification after it is needed and notifies a provider who may have moved on to another task, creating an interruption. The lower workflow in Fig. 9.4 illustrates a better workflow. The system monitors the routine OR clinical documentation workflow and the CPOE system, awaiting the indication that a surgical procedure has moved to the "closing" phase. The system fires only if there are no PACU orders by the time "closing" is documented. In the Dartmouth oximetry example, the design team eventually implemented a system in which the SpO_2 trigger was an SpO_2 of less than 80% for 30 seconds to achieve an acceptably low false-positive rate.[109] Careful attention to system design was required, and the choice of limits was not intuitively obvious.

CPOE systems are another major component of EMRs. The creation of legible orders by a person with an identifiable signature and contact information is, on its face, a major safety advance, although there have been notable problematic implementations.[110] Order writing is a potential point of risk for patients, given the dangers of dose errors, drug allergies, interactions, and side effects. But there is substantial opportunity to mitigate risk through robust decision support and self-contained safety checks that can challenge orders that violate allergy/drug interaction rules or standard dosing recommendations. A CPOE system can also allow orders to be separated by context, such that preoperative or PACU orders are separated from general care orders and become deactivated when the patient moves to a location with different monitoring standards.

CONCLUSIONS

Over the last decade, there has been an increasing focus on quality of care and patient safety as part of healthcare's larger social mandate. Organizational structures are key to establishing a culture of safety. Internal and external reporting structures currently exist to accomplish the aim of transparent outcomes and systems reporting (e.g., ACS NSQIP). These structures will need to adjust and evolve in consonance with improvements in care and recognition of previously unappreciated or underappreciated factors that disrupt care processes or affect outcomes in other ways.

Perioperative provider involvement in the maturation of these reporting structures is of utmost importance. Internal control processes, such as standardized AE reporting and investigation, coupled with multidisciplinary venues for discussion and education (e.g., morbidity and mortality improvement meetings) and linkage of findings to "just-in-time" improvement processes overseen by entities such as a perioperative quality improvement committee provide real-time institutional process control and improvement. The importance of perioperative goals and efforts that harmonize with institutional goals cannot be underemphasized. Leadership commitment to clearly enunciated goals is vital to success. Continuous education links evidence and experience to all members of the care team.

Recognizing the specific concerns and challenges that affect the intraoperative and perioperative spaces allows organizations to lend appropriate focus to those events that rely heavily on robust safety culture for management. In addition, the importance of team-based care throughout the perioperative episode is vital to integrity of the process. Essential to effective team-based care is coherent communication within and among care teams, using checklists and information technology to facilitate the care-delivery process. The recognition that physician and surgeon behaviors can have an impact on the care process has led to the development of methods and tools to identify suboptimal occurrences and initiate specific interventions using structured algorithms. Furthermore, the use of team-based training tools incorporating universal timeout and huddles/debriefs improves caregiver job satisfaction and has been shown to have a positive impact on culture-of-safety measures.

All of these processes must be built with the patient's well-being and wishes as the central guiding elements and must solicit and address feedback from patients and families. Optimized patient literacy, education, and effective communication strategies can substantively improve the overall experience.

Although the perioperative arena has begun to prioritize the highest quality and reproducibility of care, it is reasonable to assume that further growth and evolution of current systems will occur in the near future.

CHAPTER 10

Advances and Training Considerations in Robotic Surgery

Sarah Hays, Brian Boone, Herbert Zeh, and Melissa Hogg

OUTLINE

Preface
History of Robotic Surgery
Current Advances in Robotic Surgery
Culture and Perceptions of Robotic Surgery
Advances in Robotic Surgery Training
  Phase 1: Idea
  Phase 2a: Development
  Phase 2b: Exploration
  Phase 3: Training
  Phase 4: Sustainability
  Future Directions of Robotic Training
  Training Summary
Current Status of Select Robotic Operations
  Robotic Hernia Repair
  Robotic Gastric Surgery
  Robotic Bariatric Surgery
  Robotic Pancreatic Surgery
  Robotic Liver Surgery
  Robotic Colorectal Surgery
  Robotic Breast Surgery
  Robotic Endocrine Surgery
Conclusion

PREFACE

Since the da Vinci Surgical System (Intuitive Surgical, Inc., Sunnyvale, CA) was first approved by the US Food and Drug Administration (FDA) in 2000, robotic surgery has experienced a dramatic increase in use across all surgical disciplines. Over 11 million robotic surgical procedures have been performed worldwide, and thousands of peer-reviewed articles have been published reporting the safety and efficacy of robotic surgery. The field of robotic surgery has provided new definitions for optimal surgical view, operative exposure, tissue manipulation, and instrument technology during minimally invasive surgery (MIS). Overcoming previous limitations in laparoscopy, robotic surgery provides surgeons with enhanced visualization, augmented dexterity and precision, sophisticated articulating instruments, reduced fatigue, and improved ergonomics.[1]

Numerous studies have demonstrated that robotic surgery provides the benefits of MIS including decreased postoperative pain with smaller incisions, decreased blood loss, shorter length of hospital stay, and overall faster recovery compared with open procedures. Furthermore, ongoing investigation into oncologic outcomes has supported the use of the robot to treat malignant disease. Alternatively, the superiority of the robotic approach over laparoscopy has been difficult to demonstrate, and the longer operative times and higher cost of robotic surgery compared with laparoscopy pose a challenge. In addition, limited access and lack of training has inhibited the otherwise rapid adoption of the robot.

With the expiration of some of Intuitive Surgical, Inc.'s core patents, there is hope that in the coming years fierce competition will decrease the cost of the robotic platform as alternative devices enter the market. Furthermore, the cost of laparoscopy for advanced MIS procedures will likely increase as technology continues to evolve including high-definition 3D visualization and curved cameras. As costs become more comparable, it is likely that advantages such as the ease of adoption, shorter learning curve, and ergonomic superiority will further support the use of robotic surgery.

This chapter will cover the history of robotics in surgery, discuss the advances in robot technology, and investigate the evolution of training surgeons in robotic techniques. Then, the focus will turn to familiarizing the reader with the current implementation of robotic surgery within general surgery, with a focus on hernia, gastrointestinal, hepatobiliary, breast, and endocrine surgery.

HISTORY OF ROBOTIC SURGERY

Like many early advances in surgical technology, the concept of robotic surgery was born out of research funded by the military and National Aeronautics and Space Administration (NASA). This work was conducted by the NASA Ames Research Center and Stanford University in the mid-1980s, which integrated the early concepts of virtual reality with robotic surgery. The adoption of these ideas by the Department of Defense (DOD) and the Defense Advanced Research Projects Agency (DARPA) was critical for early funding.[2] The initial appeal of robotic surgery to the military was the ability to develop a way to treat critically wounded soldiers on the battlefield quickly while keeping surgeons safe.

There are three main types of robotic surgical systems: active, semiactive, and master-slave. The active system allows for the robotic platform to work autonomously while under the control of the operative surgeon, performing preprogrammed tasks. In

1988, urologists adopted the active system for use in transurethral resection of the prostate; this would ultimately become known as the PROBOT (Surgical Supplies Ltd., New Zealand), which was the first active system used in humans.[3] The semiactive system allows for surgeon-driven elements to complete preprogrammed tasks. The master-slave system, now the most used of the three options, lacks preprogrammed, autonomous elements and is dependent on surgeon activity, translating the surgeon's hand movements to laparoscopic instruments.

In 1993, Computer Motion, Inc., with funding from DARPA, developed the Automated Endoscopic System for Optimal Positioning (AESOP). This was the first FDA-approved commercial robotic arm designed to hold a laparoscope that could be controlled by the operating surgeon. This eventually became the ZEUS Robotic Surgical System (Computer Motion, Inc., Goleta, CA), which consisted of a control console that communicated to three robotic arms, one to hold the camera and two other arms to hold surgical instruments, all of which could be manipulated from the console. Using the ZEUS Robotic Surgical System, the first transoceanic, robot-assisted remote telesurgery—a robotic cholecystectomy—was successfully performed in 2002.[4] Meanwhile, researchers at Intuitive Surgical, Inc. spent much of the 1990s developing what would become the da Vinci Surgical System. Intuitive Surgical, Inc. demonstrated the feasibility of robotic-assisted surgery and the da Vinci Surgical System obtained FDA approval in 2000.[5] In 2003, Intuitive Surgical, Inc. acquired Computer Motion, Inc., subsequently dominating the field of robotic-assisted surgery.

CURRENT ADVANCES IN ROBOTIC SURGERY

Since the initial FDA approval of the da Vinci Surgical System in 2000, there have been four generations of da Vinci robots, each increasingly more sophisticated. The original da Vinci robot had three arms, one for the endoscope and two instrument arms. In December 2002, a four-arm robot was approved for clinical use by the FDA, decreasing the need for a surgical assistant and improving operative exposure. The da Vinci S system was introduced in 2006 and offered surgeons larger range of motion of the robotic arms and longer instruments, improving the ability to operate in multiple quadrants of the abdomen. This was followed by the da Vinci Si in 2009, which improved the manipulation of the robotic arms, provided high-definition visualization, and allowed for the use of a second surgeon console, which greatly improved the ability to teach trainees.[5] Released in 2014, the da Vinci Xi was notable for its overhead architecture, slimmer arms, and guided targeting, which allowed for single docking in multiquadrant surgery.[6] Most recently, Intuitive Surgical, Inc. developed the da Vinci X in 2017, which served as an entry-point robot, a less expensive alternative to the Xi. Multiple studies have shown that despite the higher cost of the Xi, the improved technology led to better perioperative outcomes and shorter operative times than the S or Si versions.[7]

More recent advances in robotic surgery have focused on single-incision surgery. Intuitive Surgical, Inc. has developed the da Vinci Single Port (SP), which allows for the introduction of the camera and three instruments through a single port (Fig. 10.1). This technology overcomes previous range-of-motion deficits associated with single-port surgery by using wristed and elbowed instruments that allow for intracorporeal triangulation. While currently under clinical trial for mastectomy, as of 2024 broader implementation of the da Vinci SP is still awaiting FDA approval.

Within the past 10 years, new robotic surgery platforms have been developed with the hopes of chipping away at Intuitive Surgical, Inc.'s market dominance. These include the Senhance Surgical System by Asensus Surgical (Durham, NC), Versius by Cambridge Medical Robotics (Cambridge, UK), Revo-i by Meerecompany (Seoul, South Korea), and Micro Hand S (Tianjin University, China). Perhaps most exciting is the development of the Medtronic Hugo RAS system (Minneapolis, MN), which has been successfully used to complete robotic radical prostatectomies in Europe and South America, and as of 2023, is working to obtain FDA approval in the United States.[8] With the development of these alternative robotic surgical systems, the hope is that competition will drive down costs, making robotic surgery a more affordable option.

The initial robotic surgery system was intended for use in cardiac surgery, but despite encouraging early results, there was limited widespread acceptance. Instead, given their experience with PROBOT (Surgical Supplies Ltd., New Zealand), urologists popularized the use of the da Vinci Surgical System for robotic prostatectomies. Now, as many as 85% of all radical prostatectomies are performed robotically, with improved postoperative recovery and functional outcomes.[9] Gynecology was the next big adopter, given the proven advantages of the robot to assist deep in the pelvis. With the ability to operate more easily in multiple abdominal quadrants, robotic surgery has become a more popular option for general surgeons performing complex abdominal operations. Intuitive Surgical, Inc. remains the current market leader in robotic surgery and estimates that, as of December 2022, over 11 million robotic surgeries have been performed and over 66,000 surgeons have been trained on the da Vinci Surgical System.[10] Robotic surgery has evolved into a billion-dollar industry that is here to stay.

CULTURE AND PERCEPTIONS OF ROBOT SURGERY

Despite the dramatic adoption of robotic techniques across general surgery over the past decade, there remains concern among the medical community. In 2019, the FDA issued a statement warning against the use of robotic-assisted surgical devices in mastectomy and other cancer-related surgeries.[11] This warning came after the results of a randomized controlled trial (RCT) that described decreased long-term survival after robotic hysterectomy for cervical cancer and cited lack of data regarding use of the robot for the prevention or treatment of any cancer.[12] A second warning against robotic mastectomy followed soon after in 2021.[13]

As of 2024, there are no large-scale clinical trials that suggest a long-term outcome benefit to a robotic approach over laparoscopy. Many of the studies that have reported an advantage to robotic surgery are small, single-center cohorts, and often are not powered to make conclusions about survival or recurrence. Meanwhile, systematic reviews have found no clear advantage with the robotic platform but have found a significant increase in cost and operative duration.[14] In 2023, a cohort study of Medicare beneficiaries found that robotic cholecystectomy was associated with a significantly higher rate of bile duct injury compared with a laparoscopic approach.[15] Accordingly, the surgical community has argued for caution and reconsideration of the utility of the robotic approach, especially when alternative, potentially safer, minimally invasive approaches exist.

Given these concerns some surgeons are advocating for better regulation of robotic surgery. Potential solutions include greater oversight of surgeon robotic credentialing and evidence-based

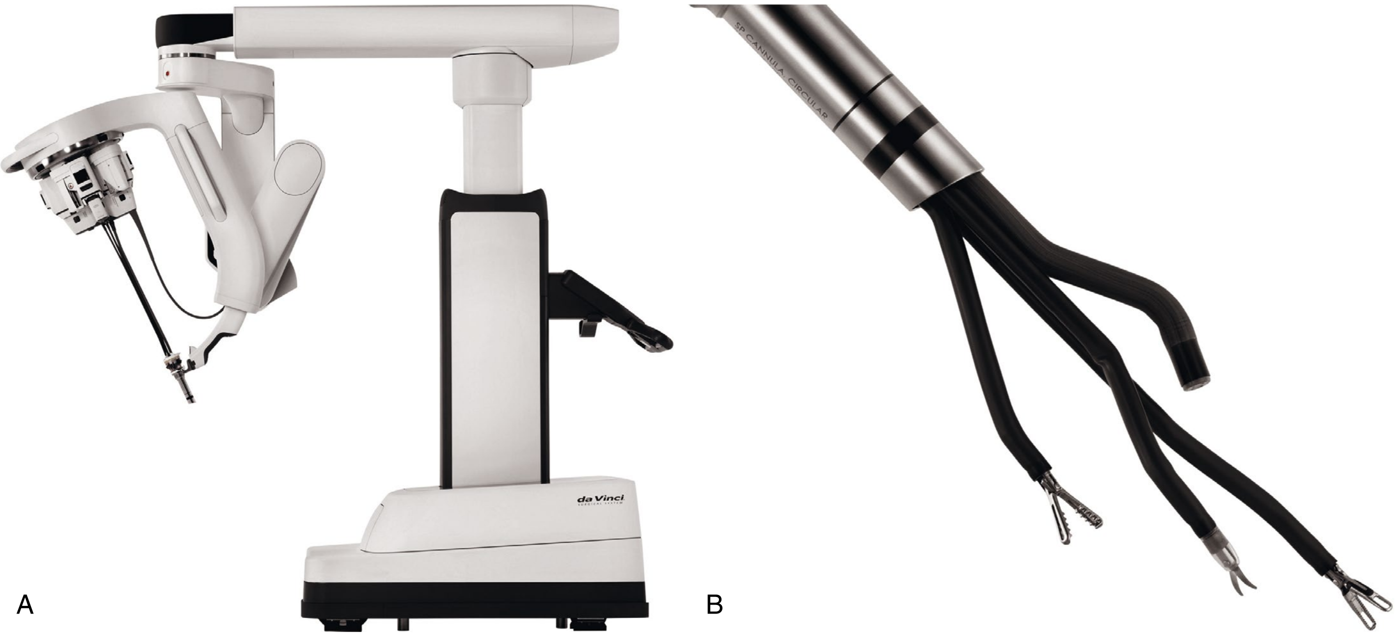

FIGURE 10.1 The da Vinci SP (2018). (A) The da Vinci SP robotic console allows for single-port robotic surgery. (B) The single-port technology allows for one camera and three instruments via a single channel, with wristed and elbowed movements. (Adapted from Intuitive Surgical, Inc.)

insurance coverage of robotic procedures. However, others see this as unnecessary red tape that will ultimately limit surgical and technologic advancement. Looking toward the future, more questions need to be answered. As artificial intelligence technology improves and the robot is able to perform entire operations with little assistance from the surgeon, who bears responsibility for poor patient outcomes? Will there be a point in the near future when a robot is supervised by a surgeon who is unable to perform the operation? As robotic surgery continues to progress, such questions will need to be answered simultaneously.

ADVANCES IN ROBOTIC SURGERY TRAINING

Since robotic surgery was first developed in the 1980s, there has been the dilemma of how to best train surgeons in this new technology. Early implementors of this technique acknowledged the need for stepwise training before performing operations in patients. The first training programs included didactic training, inanimate laboratory, animal laboratory, and cadaver laboratory all before operative observation. Furthermore, it was crucial that all team members, including operating room staff, were provided appropriate training. This section will review the advances in robotic surgical training over the past quarter century, leaning on the authors' personal experiences with the implementation of robotics in hepatopancreatobiliary (HPB) surgery at the University of Pittsburgh Medical Center (UPMC). The Idea, Development, Exploration, Assessment, Long-Term Study (IDEAL) framework outlines the stages through which surgical innovation usually passes and will be used to describe the evolution of robotic surgical training.[16]

Stage 1: Idea

In the early 2000s, the robot was predominately used in urologic and gynecologic procedures. Accordingly, some of the earliest robotic training programs were developed to train urologists on the robotic platform. The principal platform at that time, the da Vinci S robot, was a rudimentary machine that lacked high-definition imaging, energy devices, or a functional third arm and required a very cumbersome docking procedure. Despite these limitations, the robot had certain features that made it more attractive for complex minimally invasive HPB surgery over laparoscopy. It was apparent that the 2D vision, lack of articulating instruments, and long learning curves associated with the laparoscopic platform would limit the adoption of laparoscopic techniques in HPB. Recent abandonment of laparoscopy for complex HPB has supported this early conjecture.

The UPMC, with a reputation of advancement in surgical oncology technology, was an early adopter of robotic surgery. They first performed a robotic pancreaticoduodenectomy (RPD) using the da Vinci S robotic platform in 2008. While the advantages over laparoscopy were obvious, it was not clear that the technology would allow for easy adoption and the use of the robotic platform for complex HPB surgery was almost abandoned entirely. At this time, training and credentialing in robotic surgery were driven by the industry, and surgeons were only allowed to attend Intuitive Surgical, Inc. training courses after scheduling their first robotic cases. Before completing the first RPD on patients, surgeons had completed only a half-day training through Intuitive Surgical, Inc. Given this lack of training, the first two RPDs performed were proctored by a gynecologist with experience operating robotically and took over 12 hours to complete.

Stage 2a: Development

In 2009, the da Vinci Si was introduced. The more intuitive user interface, high-definition camera, third arm, easier docking, and improved energy devices proved to be significant advances. Over the course of the next 3 years at UPMC, sufficient experience was accumulated in complex robotic HPB surgery to demonstrate equivalent complication rates to large open series, and the first 50 cases were published.[17]

Critical to success of this early adoption were several factors. First, unwavering support from the institution toward innovation was essential. Second, and perhaps most important, was a commitment to a team approach. Two accomplished open HPB surgeons, who collectively had completed of over 1000 open pancreaticoduodenectomies (OPDs), worked together to successfully complete cases. The transition to the robotic platform required an enormous amount of neural reprogramming to overcome the lack of haptic feedback, in favor of "feeling" with the visual cortical pathway. The phenomenon of "robot fatigue" set in after sitting at the console for a few hours and led to headaches and psychological stress. To combat this fatigue while adjusting to the platform, the cases were split with each surgeon performing either the resection or the reconstruction, while the other assisted at the bedside. Third, the surgeons constantly reviewed outcomes and performances of each case via video recording and conducted debrief sessions to identify areas of improvement. Additionally, they used their urology colleagues to help identify best practices. Fourth, high surgeon case volume allowed for constant progression and learning. The surgeons quickly evolved from one RPD a month to one a week, which allowed for faster advancement of the entire team. Eventually, operative times were reduced closer to that of an OPD, with typical cases lasting 5 to 6 hours. After completing the first 250 cases, the learning curve for RPD was identified as 80 cases for the two early adopting surgeons.[18] At this time, it was noted that the level of commitment, the volume of cases required, and the current approach to work through the learning curve would not allow for widespread adoption of RPD and efficient progression though the IDEAL pathway.

Stage 2b: Exploration

From 2013 to 2018, robotic surgery was not widespread in general surgery. Most programs did not have access to a robotic platform, and ones that did had niche experience. Although robotic surgery was common in urology and gynecology, there was still no published dedicated curriculum for residency or fellowship training. Furthermore, the dialogue and focus were not on training but on acceptance of the adoption of robotic surgery. The adoption of laparoscopy for many general surgery procedures was mature, and the climate was pervasive that robotic surgery should not be implemented. However, with 5 years of experience implementing RPD and subsequently surpassing the learning curve, UPMC was ready to further explore with the development of a robotic surgery training curriculum.

The main focus during this time frame shifted from "can it be done?" and "can it be done safely?" to "how can it be taught to surgeons?" and how to best optimize outcomes for patients. Given the high volume of cases and a large complex general surgical oncology fellowship program, a new training paradigm at UPMC was developed. The focus of the training program was for mastery-based learning outside the operating room to decrease attention capacity for trainees and improve technical skills before patient contact. This started with virtual reality simulation.[19] The next year, biotissue inanimate simulation drills were added. The following year a video library was added. After 2 years, a five-step training program was mature and transplantable to other hospital systems. The result was improved patient outcomes while training future generations of surgeons.[20,21] The fact that the program's main focus and success were in pancreas surgery was critical. Procedures like a pancreaticoduodenectomy are considered technically difficult and thought by many to not be suitable for MIS; however, with this program there was a road map for technical adoption. Although this program was not initially successfully adopted by other fellowship or residency programs at the time, there was enough success in training attending surgeons to gain traction in the field and spin-off training programs internationally.[22,23]

Stage 3: Assessment and Training

The sustained expansion and greater acceptance of robotic surgery across general surgery and its subspecialties, particularly surgical oncology, resulted in continued advancement of robotic training for surgical trainees. The initial focus on robotic training largely began with subspecialty fellows who had already obtained open and laparoscopic skills during residency. Specific fellowship programs around the country began to adopt robotic training algorithms, and several became known as destinations for fellows with a strong interest in pursuing robotic surgical practices. Formalized fellow robotic education programs involved numerous training modalities as outlined in the following sections.

Animate Simulation

One key training advantage of robotic technology is the ability to seamlessly use virtual simulation to develop robotic skills. Simulators attached to the robot console allow for training independent of the bedside cart. Numerous drills and games are available to orient to the technology and begin to develop mastery of the console. Integrated web-based platforms allow trainees and faculty to monitor use and scores. Tasks are of varying complexity, allowing for gradual advances in robotic skillset. Later versions of robotic virtual training software even included rudimentary operations that could be performed in a step-by-step fashion.

Inanimate Simulation

Although animate simulation leads to familiarity with operation of the console, acquiring robotic skills that can be translated to the operating room necessitates learning how the robotic arms move and feel in an inanimate setting. Many of the virtual simulation drills have inanimate counterparts to accomplish the same tasks using the robot arms and instruments. Suturing and knot-tying drills are also frequently performed. Tying tightly without breaking sutures can be challenging early on due to the loss of haptic feedback, and this practice is critical to learning how to appropriately cinch knots. Complex anastomoses, including gastrojejunostomy, hepaticojejunostomy, and pancreaticojejunostomy, can be performed using lifelike biotissue. These models precisely mirror the anastomoses performed in patients during RPD. Additionally, the use of the console and patient cart during inanimate drills allows trainees to master docking and instrument exchange as the bedside assistant.

Video Review

The ease of recording during robotic procedures allows for development of comprehensive procedural video libraries in which trainees can view the surgical approach and steps to complex procedures before entering the operating room. Further, subtle technical insights can be gleaned from carefully observing experts dissecting and suturing on the robot. The videos also provide an opportunity to examine technical factors for quality improvement and research purposes.

The opportunity for formal robotic training simulation during fellowship allows for graduated responsibility in the operating room and autonomy on the console after completion of the required skill modules. The dual console system further enhances intraoperative training, allowing attending surgeons to seamlessly take control or assist robotically when necessary, which facilitates greater trainee involvement. Robotic exposure in a mentored setting allows the fellows to gain confidence in their robotic skillset and utilize the approach for actual cases, which is an invaluable start to robot use as fellows transitioned to faculty.

Indeed, comprehensive training at the fellow level results in a smoother transition to a high-volume robotic practice.[24] Further, the learning curve after comprehensive training during fellowship is nearly negligible, with early outcomes for RPD equivalent to or superior than established benchmarks post learning curve.[22] These data validate the comprehensive programs that gained popularity in the late 2010s and eventually expanded into residency programs.

Stage 4: Long-Term Study and Sustainability

Although robotic surgery was initially adopted more readily by general surgery subspecialists with complex cases, patient and surgeon preference for the robotic platform has increased the use of the robot for bread-and-butter general surgery procedures. Additionally, the robotic training curricula initially developed for attendings and fellows can easily be adapted for surgical resident training. Therefore, it has become increasingly important for general surgery residents to receive some exposure and training in robotic surgery.

As the use of robotic surgery continues to increase, there is concern that this will negatively impact general surgery resident case volume. With little to no prior experience operating on the robot, residents are frequently relegated to bedside assistant, rather than operating from the surgeon console. Providing residents with the opportunity to learn how to use the robotic platform in a low-risk setting will only help to increase resident involvement and assuage attending anxiety. Furthermore, exposure to robotic surgery at the resident level increases engagement. During one surgical residency robotic curriculum, after completing simulated laparoscopic and robotic anastomotic drills, residents not only performed better during the robotic drills, but they also preferred using the robot over laparoscopy.[25]

Resident interest in learning robotic skills is high and current residents anticipate using robotics in their future practice. However, while the majority of residents train at programs with access to a surgical robotic platform and have participated in robotic surgical cases, many have no formal training on the robot before their first case. Providing residents robotic training is feasible and effective, and multiple institutions have implemented variations of the curriculum developed at UPMC and observed subsequent improvement in robotic skill.[26,27] Although robotic curricula are becoming more common, standardization across residency programs is lacking, leading to varying skills upon completion of training. While some training is better than nothing, the development of a standardized course similar to the Fundamentals of Laparoscopic Surgery and Fundamentals of Endoscopy for robotic surgery is a logical next step in the promotion of safe robotic surgery.

Future Directions of Robotic Training

Surgical models for robotic training have largely focused on suturing drills and performance of complex anastomoses such as pancreaticojejunostomy. However, skills training for complex, open surgical resections has been largely acquired through case observation, video review, and hands-on training in cadavers. Traditionally, cadaver models are embalmed using formaldehyde and frozen to preserve tissue for education; however, this process results in stiff, unrealistic tissue texture and the loss of dissection planes. More recently, perfused cadaver models, in which the cadaver is never frozen and not embalmed, have emerged as a much more realistic alternative for learning robotic dissection and complex resection.[28] This model allows for realistic tissue plane dissection, pulsatile arteries, and full veins for recognition of anatomy and low- to high-volume hemorrhage. The ability of the console surgeon, bedside assistant, and operative team to practice hemorrhage control for complex procedures in a simulated setting is invaluable and a critical need for new adopters. Overall, the perfused cadaver model allows for close recapitulation of the technical skills necessary to safely complete complex robotic procedures.

Training Summary

The development of simulation training pathways has revolutionized the adoption of the robotic platform in pancreatic surgery. Virtual simulation and inanimate drills on a fully functional robot have been essential to training the subsequent generation of robotic surgeons. This has allowed for progression beyond the "see one, do one, teach one" paradigm that has previously dominated surgical education and allows surgeons who have never operated robotically to overcome a large part of the learning curve before ever sitting at the console to operate on a patient. After implementation of the robotic curriculum at the fellow level, the learning curve for RPD decreased from 80 to 20 cases.[29] Without the discovery of the value of simulation, it is quite possible that the adoption of RPD would have stalled.

With the shortening of the learning curve, it is very feasible for most pancreatic surgery centers of excellence to implement RPD.[30] Still, it is important to note that despite 30 years of data demonstrating that patients have superior outcomes when they have complex pancreatic surgery at high-volume centers with high-volume surgeons, most OPDs are still performed by surgeons and at centers that do less than 10 cases a year. As the field moves toward more widespread acceptance and adoption of robotic pancreatic surgery, and robotic surgery in general, the importance of robotic simulation training cannot be stressed enough. The data supporting the efficacy of these simulation pathways to safe adoption are compelling. The new robotic platforms, while easier to use than the original versions, have not yet been able to obviate the need for rigorous simulation training, and significant resources have been dedicated to refining and implementing broader access to simulation training.

CURRENT STATUS OF SELECT ROBOTIC OPERATIONS

The remainder of this chapter will discuss the use of the robotic surgical platform to perform both common and complex general surgery procedures, namely with the da Vinci Si and da Vinci Xi robotic systems. We will review the clinical outcomes for the following robotic operations: robotic ventral and inguinal hernia repair, robotic gastrectomy (RG), robotic bariatric surgery (namely Roux-en-Y gastric bypass [RYGB]), robotic pancreatic surgery (distal pancreatectomy and pancreaticoduodenectomy), robotic liver resection, robotic colectomy (RC), robotic low anterior resection with total mesorectal excision (TME), robotic nipple-sparing mastectomy (rNSM), and robotic thyroidectomy. While an extensive review, this is by no means exhaustive of all possible robotic procedures, which has increased dramatically over the past 10 years.

Robotic Hernia Repair

Robotic Ventral Hernia Repair

The laparoscopic ventral hernia repair (LVHR) was introduced in the 1990s, provided patients with an alternative to the open approach, and decreased pain, hospital length of stay, and infection rate, without increasing risk of recurrence. However, the anatomic challenges of closing abdominal wall defects laparoscopically limited the widespread adoption of LVHR. The robotic ventral hernia repair (RVHR) addresses the ergonomic limitations of a laparoscopic repair while enjoying the benefits of improved clinical outcomes compared with the open approach. The robotic approach to ventral hernia repair capitalizes on the advantages of the articulating robotic instruments such as improving the ability to close fascial defects, suture mesh in place, and close the peritoneal defect over the mesh.

The Patient-Reported Outcomes of Robotic vs. Laparoscopic Ventral Hernia Repair with Intraperitoneal Mesh (PROVE-IT) trial was the first prospective RCT to investigate the difference between postoperative pain between RVHR and LVHR. The robotic approach had a longer median operative time (RVHR 146 minutes vs. LVHR 94 minutes; $P < 0.001$) and higher cost, but there were no significant differences in postoperative pain, hospital length of stay, same-day discharge, opioid use, or overall complications. Given the increased operative time and associated cost, the authors argue that there was no measurable benefit to justify the robotic approach.[31] However, RVHR may improve long-term outcomes compared with LVHR. In one multicenter RCT comparing RVHR and LVHR there were no differences in 90-day outcomes, but at 2 years LVHR had a higher rate of hernia recurrence compared with RVHR ($P = 0.019$).[32] Although conducted in a small patient population, this trial suggests the potential benefit of decreased hernia recurrence with a robotic approach.

RCTs in support of RVHR will only further increase the use of the robot. Further work needs to be done to identify a preferred approach to RVHR. Ultimately, the potential for decreased risk of recurrence and complications may help to offset the increased cost of RVHR. Large-scale trials are needed to further assess efficacy, safety, and cost-effectiveness of the robotic approach over laparoscopic and open repair. As patients begin to request a robotic approach over their open and laparoscopic counterparts, it is important that hernia surgeons are well trained in all three options.

Robotic Inguinal Hernia Repair

Majority of robotic inguinal hernia repairs (RIHRs) were initially performed by urologists during robotic prostatectomy. With the increased availability of the robot and interest from general surgeons, the number of inguinal hernia repairs performed robotically has grown in recent years. The Michigan Surgical Quality Collaborative found that statewide, from 2012 to 2018, the use of robotic surgery for inguinal hernia repair increased from 0.7% to 28.8%.[33] This trend likely is an accurate reflection of the increased use of RIHR nationwide.

The Robotic Inguinal vs. Transabdominal Laparoscopic Inguinal Hernia Repair (RIVAL) trial (2020) was the first multicenter RCT comparing RIHR with laparoscopic inguinal hernia repair (LIHR).[34] Although there were no significant differences in clinical outcomes, RIHR was associated with a longer operative time, higher cost, and, notably, high surgeon frustration compared with the laparoscopic approach. For the straightforward hernia, the authors did not find a benefit to RIHR over LIHR.

The Prospective Hernia Study is an ongoing, multicenter analysis of clinical- and patient-reported outcomes for RIHR compared with open inguinal hernia repair (OIHR) and LIHR.[35] Early results from this study demonstrated that inguinal hernia repair can be performed effectively using any approach. Again, RIHR required the longest operative time ($P < 0.001$), but patients required less pain medications than either LIHR ($P = 0.013$) or OIHR ($P < 0.001$). Functional recovery was significantly faster for the RIHR cohort compared with OIHR (3 vs. 4 days; $P = 0.005$), but there was no significant difference between RIHR and LIHR. Postoperative complications rates were, again, comparable among the three approaches.

A 2023 prospective study has investigated the use of the da Vinci SP for inguinal hernia repair, compared with a multiport technique. The single-port repair was associated with a shorter operative time (single-port 78.1 minutes vs. multiport 93.2 minutes; $P = 0.003$), shorter recovery time ($p < 0.001$), and higher same-day discharge rate ($P = 0.001$) compared with a multiport repair.[36] Complication rates were similar between the two approaches. Although this proposes an encouraging option to decrease the longer operative time associated with RIHR, further work is necessary to validate the use of the robot for multiport and single-port inguinal hernia repair. Furthermore, as surgeons become more comfortable operating robotically, operative time may continue to decrease for multiport and single-port hernia repairs, highlighting the importance of training opportunities.

Robotic Gastric Surgery

Gastric cancer is the third leading cause of cancer-related death, and treatment requires a multimodal approach. Still, en bloc surgical resection is required for curative intent. While traditionally achieved via an open approach, laparoscopic and robotic gastrectomy have become increasingly more common. The first laparoscopic gastrectomy was performed in 1994, and since then multiple clinical trials have demonstrated the safety, feasibility, and equivalent oncologic outcomes with minimally invasive gastrectomy for gastric cancer. The technical challenges and long learning curve associated with laparoscopic gastrectomy has prompted interest in exploring the role of RG.

Due to the high rates of gastric cancer in Asia, the majority of the clinical trials investigating the role of RG come from Japan and China. In one RCT comparing robotic distal gastrectomy (RDG) with laparoscopic distal gastrectomy (LDG), the RDG cohort had faster postoperative recovery ($P < 0.05$) and reduced postoperative morbidity (9.2% vs. 17.6%; $P = 0.039$) with a greater number of lymph nodes examined (17.6 vs. 15.8; $P = 0.018$). Furthermore, the RDG patients were able to initiate adjuvant chemotherapy more quickly postsurgery (28 vs. 32 days; $P = 0.003$). This was the first RCT to compare short-term outcomes of RDG with LDG, and it demonstrated an improved postoperative course with a robotic approach.[37] These results were supported by an RCT from Japan, in which RG was again associated with a lower overall incidence of postoperative complications compared with laparoscopic gastrectomy (LG) (8.8% vs. 19.7%; $P = 0.02$).[7] Neither study has investigated long-term oncologic outcomes or overall survival; thus, they should be interpreted with caution.

In the United States, review of the National Cancer Database (NCDB) from 2010 to 2018 suggested improved oncologic outcomes with RG over LG or open gastrectomy (OG) in patients with gastric cancer. Those who underwent RG had a higher number of lymph nodes examined and a higher rate of R0 resection than either OG or LG ($P < 0.001$). Additionally, oncologic and postoperative outcomes improved for the RG cohort over the course of the study despite expanding indications for robotic resection.[38] These findings have been echoed in cohort studies, one of which noted no significant difference in 3-year or 5-year disease-free survival or overall survival rates between the robotic and laparoscopic cohorts.[39] Large-scale RCTs investigating the long-term outcomes of RG compared with laparoscopy remain necessary.

Robotic Bariatric Surgery

Bariatric surgery has been shown to be the most effective and long-lasting treatment for obesity. Classically defined by four major procedures, bariatric surgery includes RYGB, sleeve gastrectomy (SG), adjusted gastric band, and biliopancreatic diversion with duodenal switch. Laparoscopy has previously been shown to be safe and feasible in bariatric surgery. However, the ergonomics of operating laparoscopically in obese patients, where the surgeon must physically counteract the heavy abdominal wall, has prompted bariatric surgeons to explore robotic techniques. However, initial studies investigating the role of robotic surgery in obese patients found an increased risk of postoperative morbidity. In 2021, less than 12% of primary bariatrics operations were performed robotically.[40]

As of 2024, no RCTs exist comparing robotic bariatric surgery with a laparoscopic or open approach. In the United States, bariatric surgery outcomes are tracked using the Metabolic and Bariatric Surgery Accreditation Quality and Improvement Program database. Results from this database can vary significantly depending on time frame or subpopulation analyzed, which makes it difficult to draw definitive conclusions on the role of robotics in bariatric surgery. In one retrospective review of 571,417 patients who underwent laparoscopic or robotic SG or RYGB from 2015 to 2018, robotic RYGB was associated with decreased bleeding ($P = 0.0004$) and lower rate of complications ($P = 0.0013$) compared with a laparoscopic approach. Alternatively, robotic SG was associated with a higher leak rate ($P = 0.0321$), and higher readmission ($P = 0.0005$) and reintervention rates ($P = 0.0014$).[41] Among the super-obese population (BMI > 50 kg/m^2), there was similar incidence of serious adverse events for RYGB and SG regardless of operative approach.[42] Overall, despite increasing use of the robot in bariatric surgery, there is still a lack of high-level evidence comparing outcomes to laparoscopic bariatric surgery.

Robotic Pancreatic Surgery

Pancreatic operations, including pancreaticoduodenectomy and distal pancreatectomy, are considered some of the most complicated and technically challenging abdominal procedures performed by general surgeons, which are made even more challenging with a minimally invasive approach. Minimally invasive pancreatic surgery began with the first reported laparoscopic pancreaticoduodenectomy (LPD) in 1994. Still, less than 15% of all pancreatic operations in the United States are performed laparoscopically, with persistent barriers to its widespread clinical adoption mainly due to the difficulty of vascular control and high open conversion rates. Concerns over the ability to perform the proper extent of oncologic resection have further limited the adoption of minimally invasive pancreatic surgery.

Robotic Distal Pancreatectomy

The first robotic distal pancreatectomy (RDP) was described in 2003; however, most surgeons still perform laparoscopic distal pancreatectomy. Still, there remains growing interest for broader implementation of RDP. Since 2019, two RCTs have been published that investigate minimally invasive distal pancreatectomy (MIDP). The Minimally Invasive versus Open Distal Pancreatectomy (LEOPARD) trial (2019) was a Dutch multicenter study that included 47 patients who underwent MIDP (5 patients underwent RDP). Compared with open distal pancreatectomy (ODP), the MIDP cohort had a longer operative time, but had a shorter time to functional recovery, shorter length of stay, lower estimated blood loss (all $P < 0.001$), and lower rate of delayed gastric emptying (DGE) (6% vs. 20%; $P = 0.04$).[43] The Minimally Invasive versus Open Distal Pancreatectomy for Resectable Pancreatic Cancer (DIPLOMA) trial (2023) was an international, multi-institutional, randomized noninferiority trial designed to address oncologic safety of MIDP in pancreatic cancer.[44] The DIPLOMA trial demonstrated noninferiority of MIDP compared with ODP: there were equivalent rates of R0 resection (73% vs. 69%; $P_{\text{noninferiority}} = 0.039$), median lymph node harvest (22 vs. 23 nodes; $P = 0.86$), and intraperitoneal recurrence (41% vs. 38%; $P = 0.45$).[44] Additionally, median time to functional recovery and length of stay were comparable, as were 1- and 2-year survival rates. Notably, of the 131 patients who underwent MIDP, only 31 underwent RDP.[44] Although both LEOPARD and DIPLOMA trials strongly support the use of MIDP, the limited number of patients who underwent RDP demands further investigation into the true impact of the robotic approach.

Given the low number of RDPs included in the LEOPARD and DIPLOMA trials, retrospective reviews may provide better insight into the role of RDP. In an American College of Surgeons (ACS) National Surgical Quality Improvement Program (NSQIP) review, compared with ODP, the RDP cohort had a shorter hospitalization ($P < 0.0001$), lower rate of intraoperative blood transfusion ($P < 0.0001$), and lower postoperative 30-day morbidity ($P = 0.0487$), but had a longer operative time ($P = 0.003$).[45] For those patients with pancreatic ductal adenocarcinoma, the NCDB review from 2010 to 2016 showed that RDP was associated with a higher mean number of lymph nodes examined (17 vs. 15; $P = 0.002$), improved median overall survival (35.3 vs. 24.9 months; log-rank $P = 0.001$), and higher rates of 1-, 3-, and 5-year overall survival.[46] RDP was also associated with higher rates of receiving adjuvant chemotherapy (64% vs. 56%; $P = 0.017$), which has been shown to improve survival in patients with surgically resected PDAC.[47] Compared with the laparoscopic approach, RDP has been found to have improved rates of conversion, spleen preservation, and readmission to the detriment of longer duration of surgery.[48] Still early in its adoption, as surgeons become increasingly comfortable performing RDPs, operative time will likely continue to decrease.

Robotic Pancreaticoduodenectomy

In contrast to MIDP, the adoption of minimally invasive pancreaticoduodenectomy (MIPD) has been much slower, and current understanding largely relies on retrospective reviews. Compared with OPD, RPD is almost unanimously associated with increased operative time, but lower estimated blood loss; shorter length of stay; and, in many studies, increased lymph nodes examined and equivalent R0 resection rates.[49–52] There is also evidence to suggest similar median overall survival.[46] Only one study, performed at a high-volume RPD institution, found longer operative time in the open cohort.[53] Notably, in this study, all RPDs and OPDs were performed by high-volume pancreatic surgeons who were beyond their learning curve in both procedures. This suggested that as the use of RPD increases and surgeons surpass their learning curve, RPD operative time will decrease, and this may no longer be a benefit of OPD.

The improved length of stay seen in RPD patients may be due to the reduced rate of complications associated with RPD. This has been shown in many, but not all, studies and includes that patients who had RPD were less likely to have any complication (46.8% vs. 53.3%; $P = 0.004$), including major complications.[54] RPD has also been associated with equivalent to improved rates of clinically relevant postoperative pancreatic fistula, DGE, or postpancreatectomy hemorrhage when compared with OPD.[50,51,55]

Given the limited number of RPDs and LPDs performed, comparing the two is challenging. The most significant and important difference between RPD and LPD is the lower rate of conversion associated with a robotic approach. The RPD conversion rate ranges anywhere from as low as 4.1% in high-volume centers to 15% to 20% in medium-volume to low-volume centers.[56] Not only does converting to an open procedure impact length of stay and rate of complications, but it has been shown that the need to convert to an OPD increases the risk of patient morbidity and mortality.[57] Aside from conversion rate, RPD and LPD have overall similar outcomes.[51]

Despite the encouraging results of RPD, OPD remains the current standard of care and the predominant technique. In 2019, the Laparoscopic versus Open Pancreatoduodenectomy for Pancreatic or Periampullary Tumors (LEOPARD-2) trial was terminated prematurely for a nonsignificant difference in 90-day mortality (10% in LPD vs. 2% in OPD).[58] This ultimately decreased the use of LPD internationally. Recent RCTs from Europe and China have found no difference in overall morbidity and mortality between RPD and OPD, but in these two studies pancreas specific complications were observed at a higher rate than seen in the US. Ongoing RCTs, such as the DIPLOMA-2 and PORTAL trials, will be crucial in continuing to define the role of RPD in the resection of pancreatic head and neck malignancies.[59–60]

Robotic Liver Surgery

Since the late 2000s, laparoscopic liver surgery has been considered safe, effective, and standard practice for solitary, peripheral liver lesions. However, the challenges of laparoscopic liver resection, including a high rate of conversation and long learning curve, have led to increased interest in the robotic approach to liver surgery. A growing body of literature has accumulated investigating the safety and efficacy of robotic liver surgery. Compared with an open approach, robotic liver resections are associated with equivalent overall survival, but shorter hospital length of stay and lower risk of developing severe complications.[61–81] The 2023 International Consensus Guidelines on robotic liver resection suggest that a robotic approach can be considered a safe and feasible alternative to an open or laparoscopic approach for minor or major hepatectomy, hepatocellular carcinoma, colorectal liver metastasis, and living donor hepatectomy.[62]

In 2024, no RCTs exist comparing robotic to open or laparoscopic hepatectomy for primary liver cancer. However, several meta-analyses of high-quality, nonrandomized trials have found similar to improved outcomes with robotic hepatectomy. In a meta-analysis of 12 retrospective cohort studies including 1657 patients who underwent major hepatectomy, robotic major hepatectomy was comparable to a laparoscopic approach in short-term and oncologic outcomes. Notably, the robotic cohort had a significantly lower incidence of serious complications, conversion to open surgery, and postoperative hospital stay.[63]

One RCT exists investigating the role of robotic versus open resection for simultaneous resection of rectal cancer and liver metastases. In this study, the robotic cohort was associated with a lower rate of complications within 30 days postsurgery ($P = 0.014$), lower blood loss ($P < 0.001$), and shorter length of stay ($P < 0.001$). There was no significant difference in liver R0 resection rate, 3-year disease-free survival rate, or 3-year overall survival rate between the two groups.[64] Although this is a promising first study investigating potential benefits of a robotic approach to liver resection, it does not compare laparoscopy. Furthermore, there remains a need for randomized trials to investigate the role of robotic surgery in primary liver lesions.

Robotic Colorectal Surgery

Robotic Colectomy

Over the past 20 years laparoscopy has become an accepted approach for colorectal cancer surgery. With the arrival of the da Vinci Xi in 2014, multiquadrant robotic surgery became more feasible, thus increasing use of the robot in colorectal surgery. Accordingly, there has been a trend toward use of the robot over laparoscopy to perform colectomies.

There has been one notable RCT for robotic-assisted versus laparoscopic-assisted colectomy for right-sided colon cancer. In this study from South Korea, patients with right-sided colon cancer were randomized to either RC or laparoscopic colectomy (LC).[65] There was no significant difference in 5-year disease-free recurrence or 5-year survival between the two groups. On multivariable analysis, RC was not a predictor of recurrence. The only notable differences between the two groups were longer operative time (195 vs. 129 minutes; $P < 0.001$) and higher cost associated ($12,235 vs. $10,319; $P = 0.013$) with the robotic cohort. Although there was no difference between the laparoscopic and robotic cohorts, there was no benefit seen in the robotic cohort to justify the increased cost.

Retrospective reviews have further investigated the benefits of RC over a laparoscopic approach. In a NSQIP review of patients who underwent minimally invasive colectomy for colon cancer from 2012 to 2020, RC was associated with longer operative time, higher reoperation rate, and shorter length of stay, but higher readmission rate. Notably, the leak rates for right-sided colectomy were comparable, but higher for left-sided RC (3.4% vs. 2.7%; $P < 0.001$).[66] Alternatively, in another review of the NSQIP database from 2015 to 2020, RC was associated with a higher rate of "textbook outcome" than LC for both right-sided (71% vs. 64%; $P < 0.001$) and left-sided (75% vs. 68%; $P < 0.001$) colectomy.[67] Textbook outcome was defined as an absence of 30-day complications, readmission, mortality, or length of stay <5 days. Given such variation in outcomes in database studies, more RCTs in this space are crucial.

In addition to colectomy for cancer, robotic surgery has also been demonstrated to be safe in other colon pathologies. For Crohn disease, robotic ileocecectomy was found to be safe and feasible compared with laparoscopic ileocecectomy, and it may be associated with a lower complication rate.[68] Robotic sigmoidectomy for diverticulitis was associated with lower estimated blood loss, fewer postoperative complications, and lower rates of readmission and reoperation compared with a laparoscopic approach.[69]

Robotic Low Anterior Resection and Total Mesorectal Excision

For locally advanced rectal cancer, TME is the gold standard and surgical technique of choice. Despite early success of laparoscopic TME (laTME), the initial high conversion rates, high positive circumferential margins, and increased complication rates compared with an open approach attest to the difficulty.[70] Furthermore, while laTME is feasible, it is technically difficult with a steep learning curve upward of 150 cases. Alternatively, the robotic TME (rTME) allows for fine dissection in the pelvis and has a relatively short learning curve (as low as 25 cases).[71] Although the benefits of the robot over laparoscopy in colon surgery have been debated, the use of robotic surgery for rectal cancer has gained traction.

Multiple RCTs have been conducted investigating rTME. The Effect of Robotic-Assisted vs. Conventional Laparoscopic Surgery on Risk of Conversion to Open Laparotomy Among Patients Undergoing Resection for Rectal Cancer trial (ROLARR; 2017) was an international multi-institutional RCT comparing robotic versus laparoscopic low anterior resection with TME for rectal adenocarcinoma. There was no significant difference in conversion to open laparotomy, operative time, positive margins, length of stay, or 30-day postoperative morbidity or mortality.[72] This study demonstrated the safety of rTME but failed to show any superiority over laTME. Subsequently, the Comparison of Laparoscopic versus Robot-Assisted Surgery for Rectal Cancer trial (COLRAR; 2023) looked more specifically at the quality of TME and found that the robotic approach did not significantly improve the TME quality compared with laparoscopy. However, on subanalysis the positive circumferential resection margin rate was significantly lower in the robotic group (0% vs. 6.1%; $P = 0.031$). Of note, this study was terminated prematurely because of poor accrual with insufficient statistical power to assess the difference in quality of TME.[73]

One multicenter RCT from China has shown a benefit in rTME. In this study, 1240 patients with rectal adenocarcinoma underwent robotic versus laTME. Compared with laparoscopic resection, the robotic cohort had a lower rate of positive resection margin (4% vs. 7.2%; $P = 0.023$) and higher rate of macroscopic complete resection (95.4% vs. 91.8%; $P = 0.042$). The robotic cohort also had a lower rate of postoperative complications ($P = 0.003$), conversions to open laparotomy ($P = 0.021$), and a shorter length of stay ($P = 0.0001$).[74] This trial was the first to report the advantages of robotic surgery over laparoscopic surgery with regard to oncologic and postoperative outcomes. Although these short-term outcomes seem promising, the impact of the robot on long-term oncologic outcomes and long-term survival remains to be seen.

Robotic Breast Surgery

Robotic Nipple-Sparing Mastectomy

NSM provides patients with breast cancer and increased cancer risk the opportunity to maintain the external appearance of the breast while achieving comparable oncologic outcomes. Although cosmetically appealing, the nipple-sparing approach can make visualization challenging for surgeons. First described in 2015, the robotic NSM (rNSM) improves surgeon visualization and surgical retraction. However, it has been met with significant controversy, and FDA warnings specifically targeting the rNSM have subsequently stalled the adoption of this technique in the United States.[13]

The first rNSM RCT was published in Italy in 2022. Unsurprisingly, it was associated with a significantly longer operative time. However, there was no difference in complication rate or local recurrence, and the robotic cohort had higher patient satisfaction.[75] International cohort studies and meta-analyses reiterate these findings.[76,77] Techniques for robotic sentinel lymph node biopsy and axillary lymph node dissection have also been proposed and validated. While early results seem promising, more work is needed to investigate long-term oncologic outcomes and cost. Results of ongoing US and international multi-institution clinical trials for rNSM are eagerly awaited.

Robotic Endocrine Surgery

Robotic Thyroidectomy

Remote access surgery for thyroidectomy has been proposed as a way to achieve a “scarless” thyroidectomy, thus avoiding the central neck incision and relieving patient anxiety regarding the cosmetic appearance. Such approaches include an axillary approach, an anterior/breast approach, a retroauricular approach, or a transoral approach. The introduction of the robot made all these techniques more feasible, and the first robotic thyroidectomy, using a transaxillary approach, was reported in 2009. According to meta-analyses comparing the conventional open thyroidectomy to robotic thyroidectomy, each of the robotic remote access approaches have been shown to be safe and feasible in thyroid cancer.[78] The conventional open thyroidectomy is associated with a number of higher lymph nodes examined and shorter operative time, but there is no evidence that there is increased risk of complications with robotic remote access thyroidectomy.[79,80]

The most popular of the remote access approach thyroidectomies is the transoral thyroidectomy. Transoral thyroidectomy can either be performed endoscopically using a laparoscope and two handheld, laparoscopic instruments, or robotically, either using a single-port or multiport approach (Fig. 10.2). The transoral endoscopic thyroidectomy vestibular approach (TOETVA) is a shorter and less expensive operation by avoiding the use of the robot. However, the robot provides improved visualization and retraction. Compared with the conventional thyroidectomy, both TOETVA and the transoral robotic thyroidectomy (TORT) are safe options.[81,82] With growing interest in the transoral approaches for thyroidectomy, large-scale RCTs that compare the two approaches are necessary to determine whether the improved visualization with TORT improves outcomes enough to offset the increased cost.

CONCLUSION

The future of robotic surgery is bright. As the technology of the robotic platform has advanced, so too has the use of the robot across general surgery. Although the first decade of adoption was slow and riddled with doubt and opposition, the expansion during the second decade has defied all expectations. The robotic procedures that have been developed and the scale to which they have been adopted is changing the repertoire of general surgery. What once seemed like a technology confined to the abdominal cavity, robotic surgery has adapted and evolved with the goal of improving patient outcomes and satisfaction across surgical fields.

Along with broader use of the robotic technology, this second decade saw the formation of robotic training programs and the development of proficiency metrics. Once a technology that had to be learned exclusively in the operating room, robotic surgery can now be taught to all levels of surgical trainees in a simulation

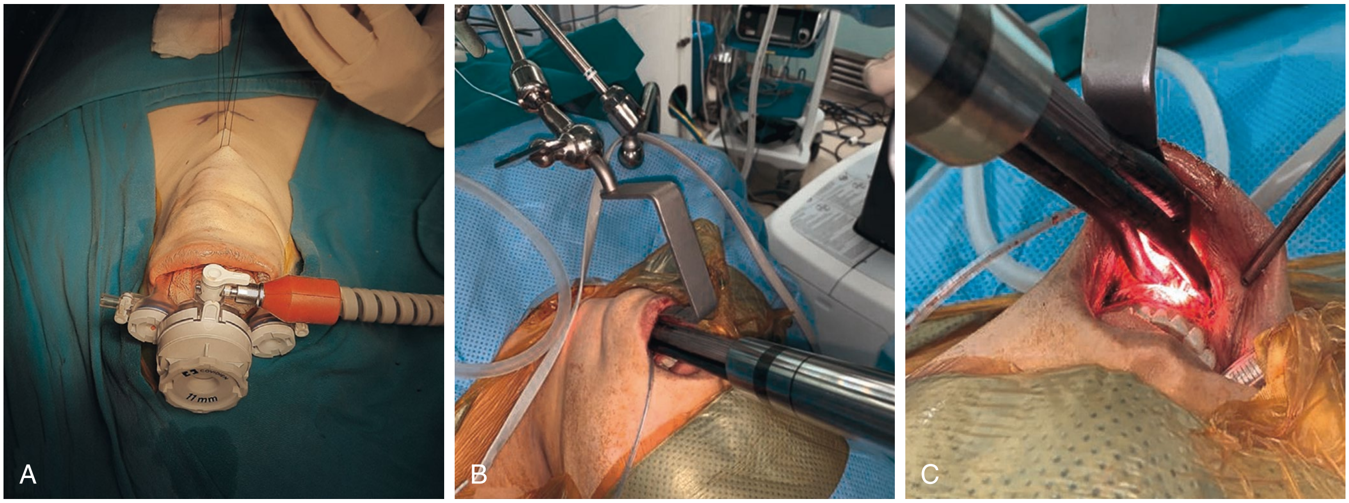

FIGURE 10.2 Transoral thyroid surgery. (A) Operative approach for transoral endoscopic thyroidectomy vestibular approach (TOETVA). (B) Operative approach for single-port transoral robotic thyroidectomy (TORT). (C) Intraoral view of single-port TORT. (Adapted from Divarci E, Ulman H, Ozok G, Ozen S, Ozdemir M, Makay O. Transoral endoscopic thyroidectomy vestibular approach (TOETVA): a novel surgical technique for scarless thyroidectomy in pediatric surgery. J Pediatr Surg. 2022;57(6):1149-1157; Park JS, Kang H, Park SY, et al. Long-term oncologic after robotic versus laparoscopic right colectomy: a prospective randomized study. *Surg Endosc*. 2019;33:2975-2981.)

environment. Current trainees not only understand the benefits of robotic surgery but plan to implement the technology in their future surgical practice.

Hopefully, the third decade will bring a more thorough incorporation of a standardized robotic curriculum into the current paradigm of surgical training, including procedure-specific mastery pathways. The doubt and opposition to robotic surgery has not dwindled, with focus now on the high cost and longer operative times with unclear long-term benefit. Ongoing research focusing on cost containment, sustainability, and comparative effectiveness studies will be critical. Competition in the industry will be welcome as long as the incorporation of new technology includes surgeon input and is more deliberately thoughtful toward training future generations of surgeons and maximizing patient outcomes.

Conclusion

INTRODUCTION

The size of an incision once symbolized a command of anatomic knowledge and technical skill. As the practice of surgery transitioned from barber shops to university lecture halls, science and technology fueled exponential growth in skills and techniques. For instance, the introduction of antisepsis and asepsis marked a pivotal shift toward minimizing tissue trauma and wound-related complications to reduce patient morbidity and mortality.[1] Surgeons continued to strive to optimize patient outcomes for various pathologies. In the early 20th century, gynecologists began challenging the convention of large incisions in surgery by inserting cystoscopes into the peritoneal cavity for diagnostic and therapeutic purposes. A turning point emerged in the late 20th century with the dissemination of the revolutionary video-laparoscopic cholecystectomy.[2] This less invasive approach demonstrated clear advantages over the traditional open surgery, including improved analgesia and reduced complications and recovery time.[3] More than a novel technique, laparoscopy significantly improved patient outcomes and would soon become an integral part of the toolkit for treating surgical disease. The subsequent rise in patient demand for less intrusive methods and industry enthusiasm for technology development led to the birth of *minimally invasive surgery* (MIS). The pursuit of "scarless surgery" has since given rise to robotic-assisted, endoscopic, and natural orifice procedures, though these are beyond the scope of this chapter. Instead, we explore advanced laparoscopic tools and techniques and highlight the role of simulation education in ensuring their safe and effective use. In addition, we discuss the implications of emerging technologies, such as artificial intelligence (AI) and augmented reality (AR), in future surgical planning and intervention. Throughout this chapter, we also assess the value and costs of these innovations when considering their integration into surgical practice.

FUNDAMENTALS

History

The foundations for modern laparoscopy were established between 1901 and 1911 by pioneer surgeons Dimitri Ott, Georg Kelling, and Hans Christian Jacobeus. Kelling, a German surgeon, conducted studies on intraabdominal bleeding in dogs. He attempted to achieve hemostasis by insufflating air into the peritoneal cavity, a technique called *air tamponade.* To observe the effects of this early form of pneumoperitoneum on the abdominal organs, Kelling introduced a cystoscope through the dog's abdominal wall, a procedure he called *koloskopie.* Operative laparoscopy was soon attempted on humans in the 1930s[2] (Fig. 11.1).

By the 1960s and 1970s, gynecologists routinely performed laparoscopic tubal ligations, ovarian cystectomies, tuboovarian abscess drainages, and pelvic adhesiolysis (see Fig. 11.1). In 1980, the gynecologist Kurt Semm, often called the "father of modern laparoscopy," performed the first laparoscopic appendectomy. Semm's procedure quickly gained recognition in the German medical community. Inspired by Semm, the German surgeon Erich Mühe developed the "galloscope" and performed the first laparoscopic cholecystectomy in 1985. He expressed, "Patients had bowel movements almost immediately after the surgery and could eat supper the same evening…the approach was like magic." Mühe presented his work on 94 successful laparoscopic cholecystectomies at the 1986 Congress of the German Surgical Society but faced criticism from a community unprepared for the era of MIS. At this time, abdominal surgeons focused on extensive operations such as organ transplantation and oncologic resections. Furthermore, the German healthcare system incentivized extended hospital stays over improved patient outcomes. Mühe's work was consequently dismissed as "Mickey Mouse surgery." He even faced manslaughter charges after the death of one patient because of surgery-related complications. In 1987, French gynecologist Philippe Mouret performed the first "globally accepted"

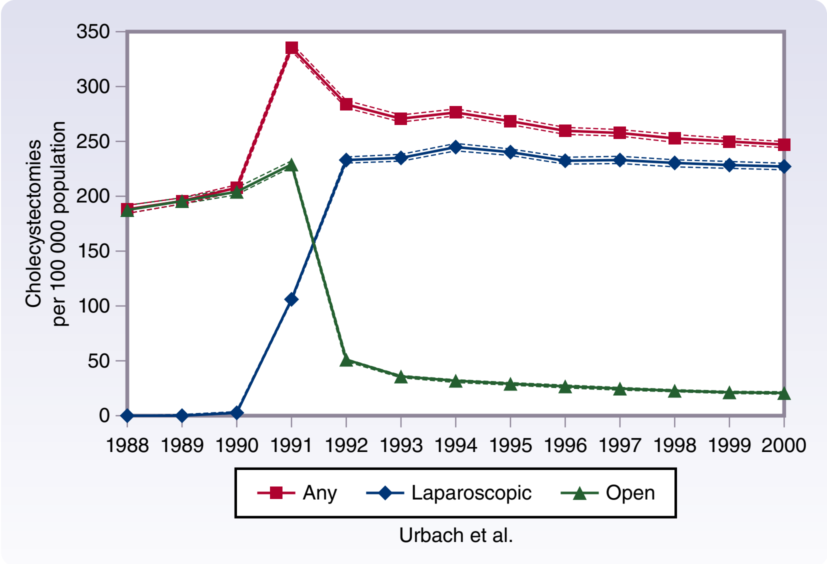
laparoscopic cholecystectomy, sparking the revolution of laparoscopy in surgical care.[4] Over the next 2 to 3 years, the laparoscopic cholecystectomy rapidly spread worldwide due to advantages such as reduced postoperative pain, quicker recovery, improved cosmetic results, shorter hospital stays, and faster return to work than the open cholecystectomy.[3,5–8] This minimally invasive approach was not without complications, however. Major complications, including biliary tree injury requiring Roux-en-Y hepaticojejunostomy for proper biliary drainage, were associated with inadequate surgeon training and a lack of experience.[5,9] Surprisingly, only half of practicing surgeons who performed a laparoscopic cholecystectomy between 1989 and 1991 completed the recommended training sequence outlined in the early Society of American Gastrointestinal and Endoscopic Surgeons (SAGES) guidelines.[10] Because of these alarming data, there was significant pressure to ensure high-quality care in a rapidly advancing technologic environment, leading to the inclusion of laparoscopic training in the general surgery residency curriculum.[11–13] This decision was supported by evidence showing that surgical trainees could perform a laparoscopic cholecystectomy with similar complication rates and outcomes to experienced surgeons.[14] By 2000, the approach to the cholecystectomy was dominated by laparoscopy, as illustrated by the steep drop in the number of open cholecystectomies performed (Fig. 11.2).[15,16] Other open procedures rapidly followed suit, including inguinal hernia repair, gastrectomy, appendectomy, and colectomy[17] (see Fig. 11.2).

This shift in surgical approach had a significant impact on residency training as well. Initially performed only by attending surgeons, laparoscopy is now introduced early in residency. Laparoscopic skills training has since been formally integrated into surgical curricula. Assessments of laparoscopic skills are conducted through the Fundamentals of Laparoscopic Surgery (FLS) Examination, a requirement for graduates from US residency programs and implemented worldwide. The development of laparoscopic skills in the operating room is complemented by dedicated simulation education centers where high-fidelity models, box trainers, and AR/virtual reality simulators are used to replicate procedures. As the American Board of Surgery (ABS) now champions a paradigm shift of competency-based education over



Urbach et al.

FIGURE 11.2 The introduction of laparoscopy in Canada in 1991 led to a significant shift from open to laparoscopic approaches for cholecystectomies. (From https://www.cmaj.ca/content/172/8/1015.)

the number of procedures performed or years of residency completed, laparoscopic skills continue to be highly valued in training competent general surgeons.[17]

Preoperative Considerations

Before proceeding with laparoscopic surgery, modern surgeons must carefully consider several factors to ensure patient safety and technical success, such as patient selection, room setup, and equipment.

Patient selection is of paramount importance. Determining whether a patient can tolerate high intraabdominal pressure and positioning is crucial. Visualizing and manipulating intraabdominal structures relies on pneumoperitoneum, which is achieved by introducing carbon dioxide into the abdominal cavity. Adequate visualization of the operative field also requires the patient to be appropriately positioned, sometimes in extreme positions, to harness the power of gravity to shift intraperitoneal organs. Hence, surgeons must assess patients' ability to withstand these conditions and their medical and surgical histories during a preoperative evaluation. Cardiopulmonary health is of particular concern, given the impact of pneumoperitoneum on cardiac and pulmonary function. Patients with conditions that affect venous return or lung compliance may not be suitable candidates for laparoscopy. Additionally, surgeons should elicit a history of deep venous thrombosis because laparoscopy increases the risk of venous thromboembolism (VTE) secondary to prolonged operative time and pneumoperitoneum-induced inferior vena cava compression. Prior abdominal surgeries should also be reviewed, as they can lead to adhesive disease, complicating abdominal access and tissue manipulation during surgery. A comprehensive physical examination is also essential. Surgeons should assess for umbilical abnormalities, prior abdominal incisions, and ascites, which can affect abdominal access and trocar placement (Fig. 11.3). Evaluating the patient's range of motion in the arms and hips is essential to anticipate positioning limitations in the operating room. Although laparoscopy has been proven highly versatile, specific absolute contraindications exist. Patients with massive abdominal distention that hinders safe insufflation or unstable hemodynamics who cannot tolerate pneumoperitoneum should not undergo laparoscopy. Furthermore, patients with severe systemic diseases for whom a possible laparotomy would pose a prohibitive risk should not be offered any surgical approach, including laparoscopy, because there is always a possibility of conversion to open surgery.[18,19]

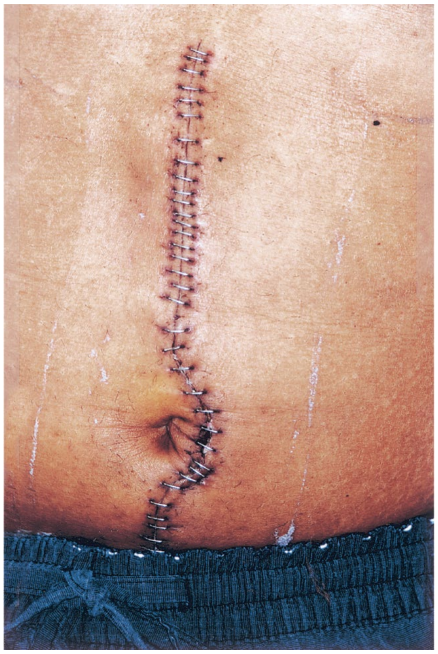


FIGURE 11.3 Midline incision on the belly of a patient. (From Chabner DE. *Medical Terminology: A Short Course*. 9th ed. St. Louis: Elsevier; 2023.)

A range of essential equipment is needed to perform laparoscopy, including imaging, insufflation, electrosurgery, irrigation, and aspiration systems. Insufflation, a crucial step in laparoscopy, is achieved using an insufflator device that delivers carbon dioxide gas into the peritoneal cavity through a needle or trocar. Carbon dioxide is preferred because it rapidly dissolves in blood, is nonflammable, and carries a low risk of gas embolism. The gas flow rate can be adjusted to maintain optimal intraabdominal pressure (10–15 mm Hg). Intraabdominal pressures above 25 mm Hg can lead to complications, such as gas embolism, acidosis, and decreased venous return. Laparoscopic imaging has evolved significantly from eyepieces to advanced camera systems. The laparoscope, equipped with a camera at its distal tip, captures images with illumination from an attached light source. The digitized images of the peritoneal cavity are then transmitted, reconstructed, and displayed on a monitor. Different laparoscope diameters (5 and 10 mm) and camera angles (0, 30, 45, and 50) can be used to optimize visualization (Fig. 11.4). Image quality and clarity can be optimized by white-balancing the camera, focusing the lens, and warming the laparoscope to avoid condensation-induced lens fogging. Specialized irrigation and aspiration systems are used to maintain an unobstructed operative field during laparoscopic procedures. Lactated Ringer solution is a commonly used irrigant. The suction instrument can evacuate fluid or smoke produced by electrosurgical tools from the operative field. Prolonged suction can, however, lead to the loss of carbon dioxide gas and decreased intraabdominal pressure. Specific smoke evacuation devices can limit this effect. Electrosurgical devices are used to achieve hemostasis. These devices often rely on high-frequency electrical currents to cut and coagulate tissues. Monopolar electrosurgery employs various active electrode probes such as spatulas, hooks, forceps, scalpels, and scissors (see Fig. 11.4). Notable advancements in laparoscopic electrosurgery include bipolar electrosurgery and vessel sealing technology. To avoid electrothermal injury, surgeons should keep the electrode tip visible to prevent unrecognized energy transfer and exercise caution around the conductive metal clips and instruments to avoid direct coupling.[18,20,21]

Given the extra equipment required for laparoscopic surgery, room size and door location must be considered when designing operating rooms specifically for these procedures. In addition, staff should anticipate the necessary positions of monitors, connecting cables, and additional equipment to avoid situations that may disrupt efficiency. Setup should be completed before the patient enters the operating room to ensure a seamless operation. Equipment checklists are helpful to ensure that all necessary items are available and functioning correctly. Once the operating table is positioned and oriented, the video monitors should be placed directly opposite the surgeon's and assistant's points of view. For example, during a laparoscopic cholecystectomy, the surgeon stands on the patient's left side, opposite the target pathology, whereas the assistant stands on the patient's right side. The remaining equipment and associated lines should then be

positioned on the same side as the person using them and ultimately secured to the surgical drapes in a way that does not hinder mobility (Fig. 11.5). Although prefabricated drapes with gutters and pockets are available, specific arrangements may vary among institutions and providers[21] (see Fig. 11.5).

Patient positioning on the operating table is a crucial step in preparation for surgery. Sequential compression devices are applied after the patient is transferred to the operating table. These are essential as laparoscopy is associated with an increased risk of venous stasis and thromboembolism secondary to pneumoperitoneum-induced caval compression and prolonged operative time. The patient is then securely fastened to the table using restraints to avoid injuries from excessive hip/shoulder abduction or Trendelenburg/reverse Trendelenburg positioning, which harnesses gravity to provide optimal organ exposure. For example, the Trendelenburg position (head lower than the feet) enhances access to the lower abdominal and pelvic organs. Conversely, the reverse Trendelenburg position (feet lower than the head) improves access to the upper gastrointestinal (GI) tract and biliary tree. Footboards or other supports may minimize patient shifting during positioning. To reduce the risk of iatrogenic injury to the bladder or stomach during abdominal entry, a urinary catheter or nasogastric tube may be inserted for decompression after the induction of anesthesia, depending on the specific procedure. Likewise, the

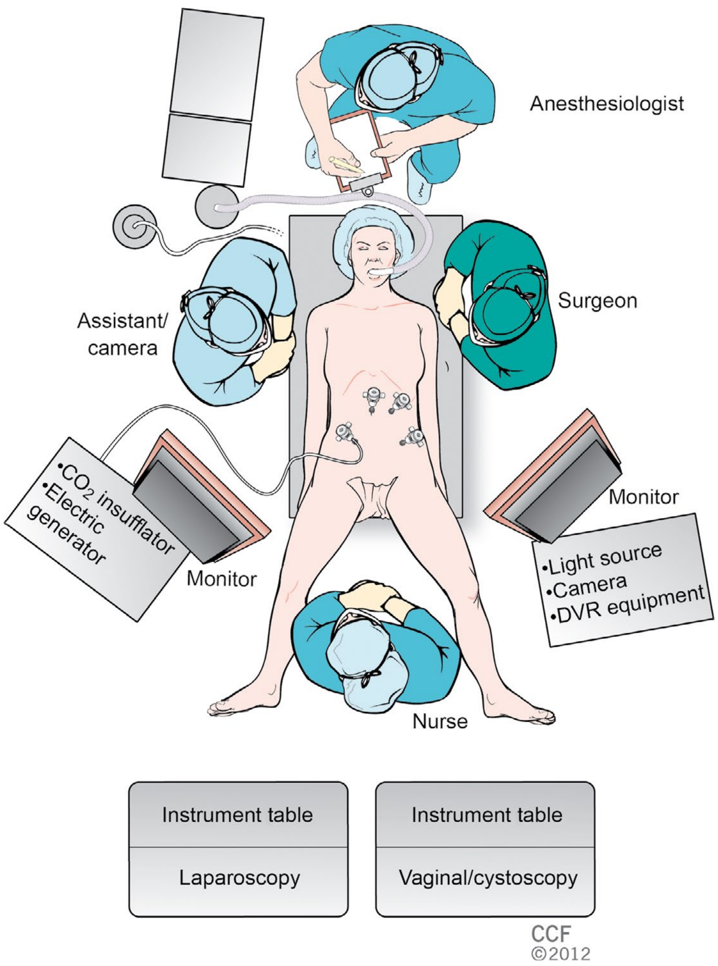

FIGURE 11.5 Operating room setup for operative laparoscopy. (From Tarr ME, Paraiso MFR. Laparoscopic and robotic surgery for pelvic organ prolapse and stress urinary incontinence. In: Karram MM, Walters MD, eds. *Urogynecology and Reconstructive Pelvic Surgery*. 4th ed. Elsevier; 2015.)

patient's position on the operating table, most commonly supine, split leg, modified lithotomy (used for pelvic operations with legs secured by Allen stirrups), or lateral decubitus (e.g., splenectomy, adrenalectomy, and thoracoscopic), depends on the specific surgical procedure being performed (Fig. 11.6).[18]

Research in ergonomics, the science of efficient and safe interaction between people and objects, has proposed various improvements to the minimally invasive surgical environment. The impact on surgeon longevity and patient safety has been suggested based on correlative evidence in fields such as piloting and professional driving but has yet to be demonstrated. For example, incorporating floor and overhead lights with remote repositioning options can balance the need for dim lighting in an otherwise high-risk, darkened work environment. Ceiling-mounted monitors with adjustable positions and gaze-down viewing options can help maintain optimal body and neck positions. Instrument manufacturers could consider a range of hand and body sizes to accommodate the increasing percentage of females in the surgical workforce when designing laparoscopic instruments. Finally, eliminating excessive cables and tubes, particularly those associated with floor-stationed foot pedals, may significantly improve safety and operating efficiency. As the link between workplace ergonomics, surgeon longevity, and patient safety increases, creating universally accepted ergonomic guidelines and widespread awareness is necessary.[21]

Intraoperative Procedures

The peritoneal cavity must be entered before the insufflation of carbon dioxide gas, which creates space between the abdominal wall and intraabdominal organs to enable visualization and instrument mobility. The approach to initial abdominal access has evolved. Initially, Kelling introduced atmospheric air into a dog's peritoneal cavity through an abdominal trocar. Along with experimenting with different insufflation media (Richard Zollikofer, a Swiss gynecologist, ultimately discovered the benefits of using carbon dioxide gas), surgeons sought innovative ways to access the peritoneal cavity without damaging intraabdominal organs.[22] In the late 1930s, Hungarian internist János Veres published his work on an insufflation needle with a unique spring-loaded cannula designed to induce pneumothorax for treating tuberculosis. In the 1940s, Raoul Palmer adapted the Veres needle to establish pneumoperitoneum, solidifying its role as a standard laparoscopic tool. However, blind insertion of the Veres needle was felt to carry a risk of visceral and vascular injuries, preperitoneal insufflation, and gas embolism.[23] In the 1970s, Harrith Hasson, an American gynecologist, introduced an alternative "open" trocar placement method that allowed for the direct visualization of a trocar during its insertion into the peritoneal cavity through a blunt minilaparotomy.[24] He developed a three-piece reusable device akin to a standard cannula but with an olive-shaped sleeve that slid along the cannula shaft to form an airtight seal at the fascial opening. The sharp trocar used for "closed" entry was replaced with a blunt obturator. Once inserted, this cannula could be secured to the abdominal wall with stay sutures passed through the fascial edges. "Closed" and "open" techniques continue to be used today for abdominal access. Data suggest that the overall complication rates do not significantly differ between the Hasson and Veres needle techniques when performed by experienced surgeons.[25] Although comprehensive operative guides such as the SAGES manual[21] offer instructions for executing these procedures, we examine the general principles and theories in this section[21] (Fig. 11.7).

In the closed technique, a scalpel is used to create a stab incision, and a Veres needle is inserted. Common access sites include the cranial or caudal border of the umbilicus or the left subcostal region (Palmer point). The umbilicus may be preferred for entry because the fascia layers are fused at the linea alba at this location. If the patient has a lower midline scar from prior surgery, the abdomen can be accessed at the lateral border of the rectus muscle in either the left or right upper quadrants. Decompressing the stomach (e.g., nasogastric, orogastric tube) may help avoid visceral injury for left-sided access. For right-sided access, percussing the liver edge may also be helpful. The abdomen can be accessed in the right lower quadrant if there is an upper midline scar from prior surgery. In these cases, bladder decompression (e.g., preoperative void or urinary catheter) should be considered to avoid visceral injury. Next, the Veres needle is held like a dart and advanced through the abdominal wall layers until it enters the peritoneal cavity (see Fig. 11.7). The instrument's blunt tip retracts and reveals a sharp needle when it encounters resistance at the fascial and parietal peritoneal layers. Gentle twisting of the needle can facilitate passage, and gentle bouncing may be helpful to identify resistance at wall layers or free movement in the peritoneal cavity. Once resistance subsides, the blunt tip springs forward to shield the sharp needle and prevent intraabdominal organ damage

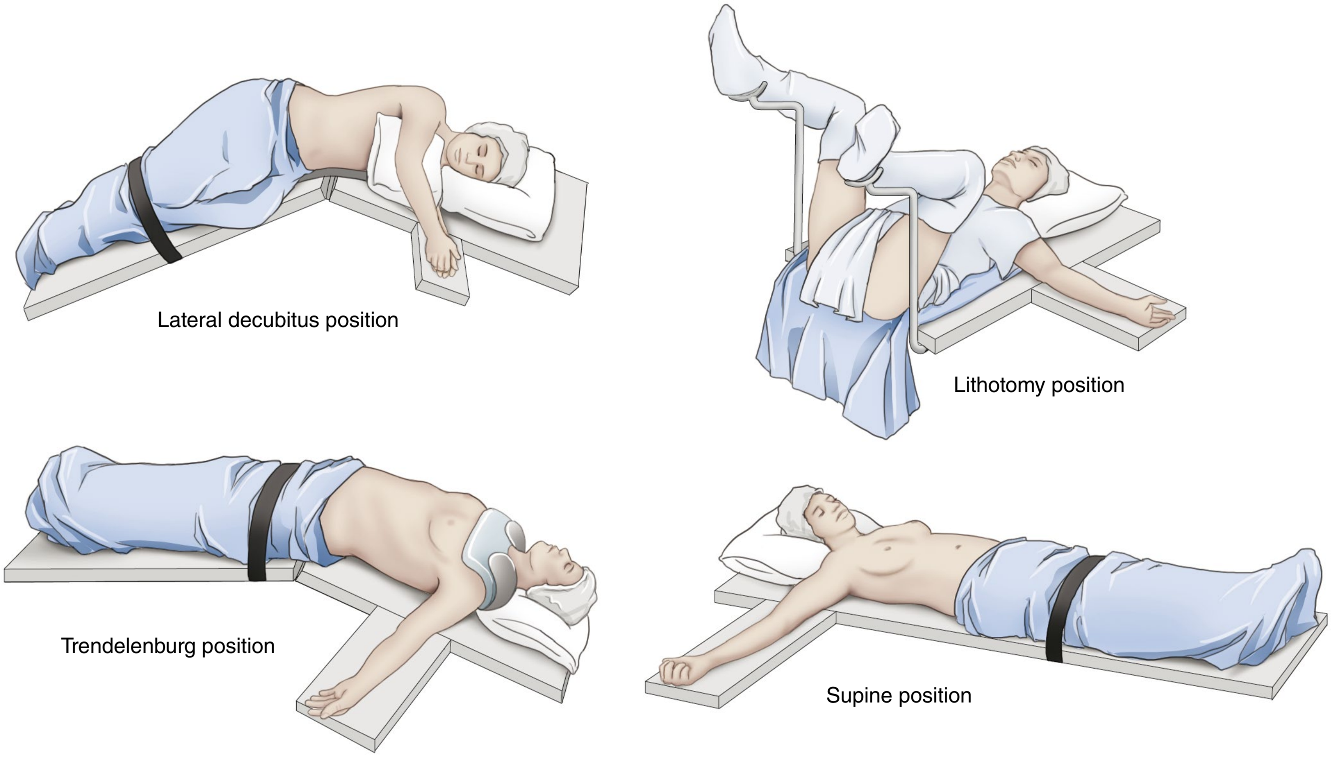

FIGURE 11.6 Positions on the operating table. *Top left,* Lateral decubitus position. *Top right,* Lithotomy position. *Bottom left,* Trendelenburg position. *Bottom right,* Supine position. (From Stein LNM, Hollen CJ. Perioperative care. In: *Concept-Based Clinical Nursing Skills: Fundamental to Advanced Competencies*. 2nd ed. Elsevier; 2024.)

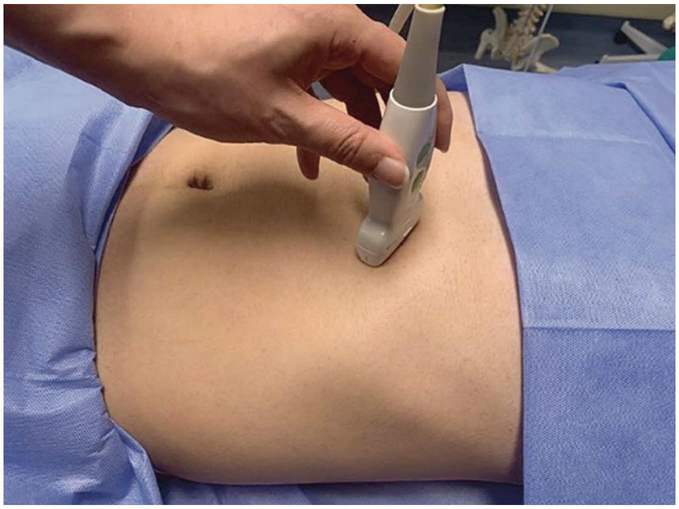
(Fig. 11.8).[21] Various syringe-based tests, such as aspiration or saline instillation, can be performed to ensure that the needle tip is correctly positioned in the peritoneal cavity. However, there is no literature evidence supporting these tests. Instead, the initial intraperitoneal gas pressure upon connection of the insufflation line to the needle serves as a reliable indicator for determining the location of the needle tip.[26] Abdominal pressure should remain below 10 mm Hg during initial insufflation. If the abdominal pressure remains high (quickly climbing to 15 mm Hg), despite gentle needle adjustment, the instrument should be withdrawn and reinserted. During initial insufflation, the patient should be monitored for bradycardia/hypotension (parasympathetic peritoneal stretch response). As carbon dioxide fills the peritoneal cavity, the abdominal wall should expand symmetrically, and the sharp costal margin contours should fade (see Fig. 11.7). After full pneumoperitoneum is achieved, the initial port may be placed using either a basic sharp trocar (blind method) or a blunt optical trocar. The remaining ports are placed under direct laparoscopic imaging guidance (see Fig. 11.8).

In the open or “Hasson” technique, the operator visualizes all the abdominal wall layers directly during the initial access phase. Although originally designed to address concerns regarding abdominal wall adhesions in patients with prior abdominal surgeries, the Hasson technique is used consistently by some surgeons today. The procedure begins with a 2- to 3-cm incision made either in a periumbilical skin crease or, if the patient has a midline scar from a previous abdominal surgery, in a quadrant farthest from the scar. The subcutaneous tissue is dissected sharply (with scissors), bluntly (with S retractors), or with monopolar electrosurgery. Once the fascia is exposed, it is sharply divided (Fig. 11.9). The parietal peritoneum may sometimes be divided simultaneously or simply grasped and divided if intact. Entry into the peritoneal cavity is confirmed with visual assessment and digital palpation. Two separate #0 absorbable sutures are placed along the fascial edges to maintain a secure seal and to prevent pneumoperitoneum loss during the procedure. These sutures can also aid in reapproximating the fascial edges at the end of surgery. Subsequently, the Hasson trocar and blunt obturator are inserted, and the fascial sutures are wrapped around the sheath’s struts. With the insufflation line connected to the trocar, pneumoperitoneum is established with an intraabdominal pressure goal of 10 to 15 mm Hg.[18,21] If a carbon dioxide leak around the Hasson trocar is detected, balloon-tipped trocars can be used to help achieve an adequate seal at the abdominal wall (see Fig. 11.9).

Regardless of the method used to access the peritoneal cavity (either open or closed), it is essential to carefully consider port placement to ensure efficiency and efficacy during the procedure. Although port placement may vary slightly depending on the surgery, institution, or surgeon, understanding the underlying concepts remains crucial. Generally, there are three categories of ports: optical, operative, and assistive. However, their roles can interchange during the operation. The primary port for creating pneumoperitoneum is typically the largest trocar. After initial trocar placement direct visualization while placing additional operative or assisting ports is used, thus minimizing potential harm to the intraabdominal organs. Operative ports are usually placed approximately 10 to 15 cm from the target organ and spaced far enough apart to avoid the “crossing swords” effect (e.g., maintaining a



First Aid Perioperative Ultrasound

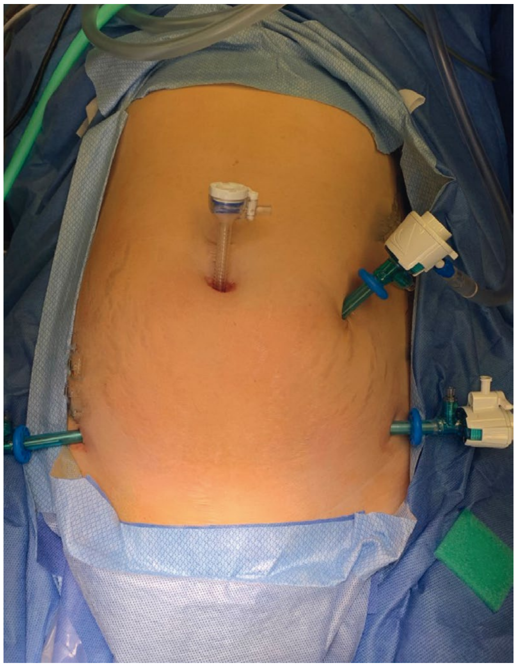


FIGURE 11.7 Laparoscopic ports. (From Recknagel JD, Goodman LR. Clinical perspective concerning abdominal entry techniques. *J Minim Invasive Gynecol.* 2021;28(3):467-474; https://vardhmanhospital.com/Jain_point_A_new_safe_portal_for_laparoscopic_entr.pdf.)

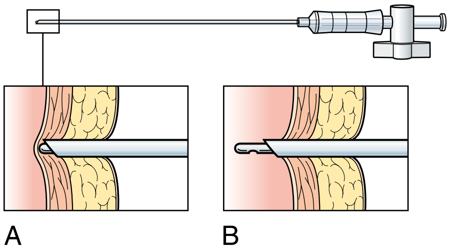

FIGURE 11.8 A Veress needle. (A) The needle is just about to pierce the inner lining of the cavity. (B) As soon as the needle has entered the cavity, the round-ended, spring-loaded obturator projects, pushing away any structure that might be punctured by the sharp needle and exposing the gas inlet. FIGURE 11.9 The Hasson technique. The Hasson trocar is placed through the incision after the fascia and peritoneum are incised. (From Dall CP, Atalla MA. Ports and establishing access into the peritoneal cavity. In: Kavoussi LR, Bishoff JT, Kavoussi N, Bishoff T, eds. *Atlas of Laparoscopic and Robotic Urologic Surgery.* 4th ed. Elsevier; 2023.)

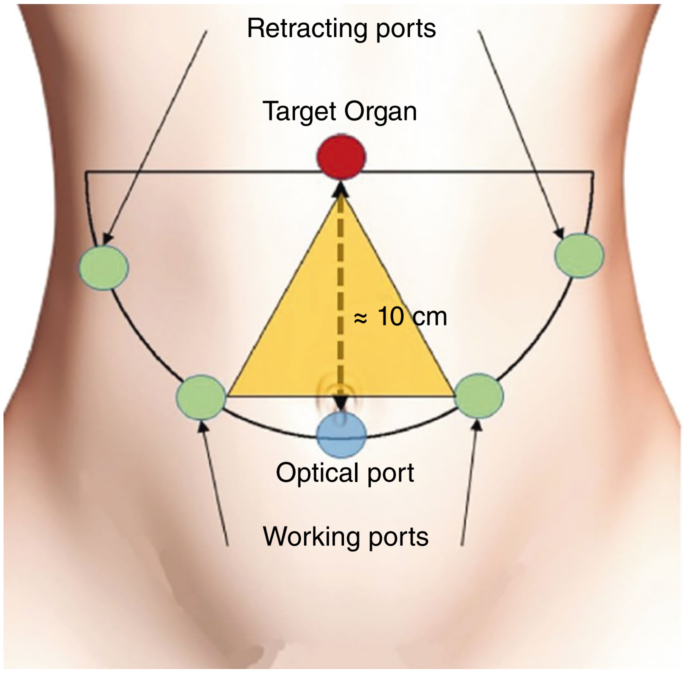
60- to 120-degree angle between ports). Assistive ports enable surgeons to retract or expose their operative field. Ideally, these should be positioned approximately at least 4 to 5 cm from the operative ports (Fig. 11.10). When closer to the operative site, assistive ports enhance mediolateral retraction, whereas positioning them further enhances craniocaudal retraction. During port placement, damage to superficial abdominal vessels can be avoided by transilluminating the proposed trocar site from inside the abdomen using a video laparoscope. Once the optimal location is identified, a skin incision matching the trocar diameter is made using a scalpel. The trocar is inserted through the abdominal wall layers with a slow, steady twisting motion and consistent pressure under direct laparoscopic imaging guidance until the sheath enters the peritoneal cavity. If a trocar is noted to be dangerously close to an intraabdominal organ, methods such as increasing intraabdominal pressure or lifting the skin can help increase the distance between the threatened viscera and the abdominal wall. Instruments placed through other trocars can also provide counterpressure. Alternatively, the trocar entry angle can be adjusted to be more parallel to the anterior abdominal wall.[18,21] If challenges are encountered during the procedure, it is worth considering the addition of an extra port for dissection, resection, reconstruction, extraction, or retraction instead of converting to an open operation.

Like open surgery, laparoscopic dissection aims to separate tissues while ensuring hemostasis. However, laparoscopy has inherent limitations that increase the difficulty of achieving meticulous hemostasis and preventing accidental tissue damage, such as decreased tactile sensation and instrument mobility. The two-dimensional (2D) view provided by video-laparoscopy can be further compromised by subpar video quality and illumination. Effective laparoscopic dissection is usually performed using a two-handed



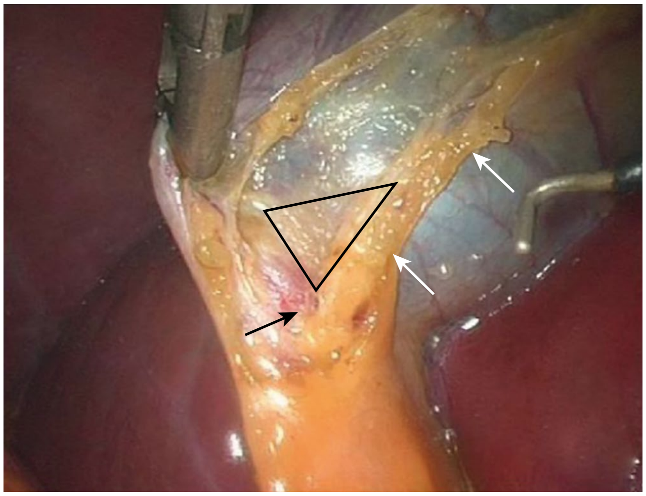
ESPES Manual of Pediatric Minimally Invasive Surgery

FIGURE 11.10 Surgeons should aim for ergonomic port placement. Place retracting ports far laterally to manipulate the target organ. Position the optical port centrally for optimal visual access, and situate the working ports between them to ensure good instrument mobility. (From Zachariou Z. Ergonomics in minimally invasive surgery. In: Esposito C, Becmeur F, Steyaert H, Szavay P, eds. *ESPES Manual of Pediatric Minimally Invasive Surgery*. Cham: Springer; 2019.)

approach. An assisting tool, typically a grasper, provides counter traction and exposure to a dissecting tool. This active tool can be either nonenergized (e.g., scissors or a grasper) or energized (e.g., electrosurgical or ultrasonic instruments). There are three main types of dissection: blunt, sharp, and electrosurgical. Concurrently, many dissecting tools are available to emulate the instruments used in open surgery and compensate for the limitations unique to laparoscopic surgery. Blunt dissection involves stripping and wiping to separate tissues. Although these methods are safe and effective, they have limited hemostatic capacity and are best for avascular planes. Sharp dissection employs scissors or scalpels for accurate tissue cutting, fine spreading, and grasping. This method is good for precise dissection in avascular or scarred planes. Many commonly used dissectors feature tapered tips that fall between sharp and blunt shapes. For example, the Maryland and right-angle dissectors have curved and angled tines that facilitate dissection around structures and enhance illumination and visualization of the instrument's tips.[27] Finally, electrosurgical dissection is highly effective at achieving hemostasis but carries the most significant risk of injury among the dissection techniques. Thermal damage to nontarget internal organs can result from the imprecise mechanical operation of an electrosurgical tool or from the electrical current being diverted away from the intended path (Figs. 11.11 and 11.12).[28]

Tissue separation in laparoscopic surgery aims to excise diseased organs and enable their subsequent reconstruction. MIS has witnessed a swift advancement of tools for tissue resection and reconstruction, such as staplers, clip appliers, and ligating loops, driven by a booming interest in laparoscopy and the need to reduce the technical demands associated with laparoscopic suturing and knot tying (Fig. 11.13). Surgical staplers have emerged as versatile instruments for organ resection, vessel/duct ligation, and anastomosis creation. Laparoscopic clip appliers are also used to ligate small vessels and ducts but are generally avoided for large hollow viscera and blood vessels.

Ligating loops offer another option for ligating structures such as the cystic duct or appendix (Fig. 11.14). Tissue fasteners are an alternative to laparoscopic suturing and can be used to secure mesh to the anterior abdominal wall for a hernia repair. Finally, tissue adhesives can close skin incisions, achieve hemostasis, and support vascular and GI anastomoses. With the evolution of laparoscopic tools, we look forward to evaluating the role of novel



Almutairi et al.

tissue approximation devices, such as tissue welding or surgical magnets, in the clinical environment.[21]

Once an abdominopelvic organ is resected, it must be removed from the peritoneal cavity. However, MIS presents the unique challenge of extracting large, diseased organs through small incisions. There is also a potential risk of wound infection when removing an infected organ through an unprotected wound. Specimen retrieval bags have been designed and widely adopted to address concerns about wound protection. However, recent studies have questioned their effectiveness. For example, specimen retrieval bags do not affect rates of postoperative surgical site infection in cases of uncomplicated and complicated appendicitis.[29] Likewise, they do not prevent wound infections in patients undergoing elective laparoscopic sleeve gastrectomy or cholecystectomy.[30] However, the potential risk of port site malignancy when a cancerous organ is removed through an unprotected wound is well known.[31] Therefore, specimen retrieval bags still play a vital role in these cases. Nevertheless, extracting a benign large diseased organ through a small incision remains challenging. Specimen retrieval bag–facilitated specimen morcellation has emerged as a solution for benign specimens. For example,

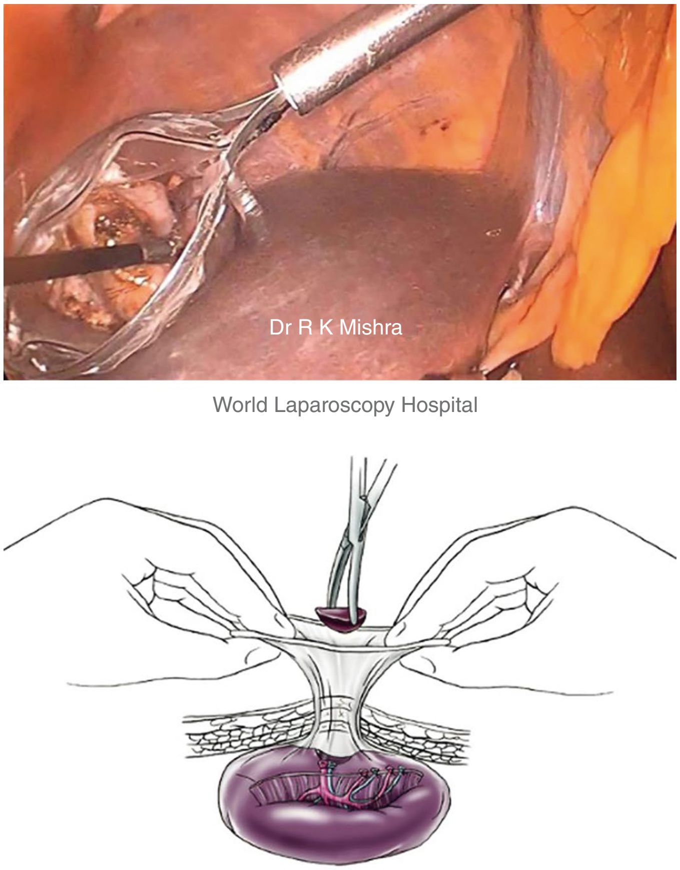

FIGURE 11.15 *(Top)* Specimen retrieval bag used to collect and extract the gallbladder during a laparoscopic cholecystectomy. *(Bottom)* Mechanical fragmentation of the spleen within a retrieval bag involves manually breaking the spleen into smaller pieces while contained in a specialized bag to facilitate the removal of an otherwise relatively large organ through a laparoscopic port. (From Skandalakis JE, Skandalakis LJ, Skandalakis PN, Sweeney JF. Spleen. In: Wood WC, Staley CA, Skandalakis JE, eds. *Anatomic Basis of Tumor Surgery*. Berlin, Heidelberg: Springer; 2010.)

mechanical fragmentation of the spleen within a bag after splenectomy reduces the risk of splenosis while allowing tissue extraction through a small incision (Fig. 11.15). However, morcellation is avoided in oncologic surgery for two reasons. First, it eliminates the tumor margins pathologists use for disease staging, and second, it risks cell transfer or spillage, which can contaminate nearby tissues and structures with cancer cells. Hand-assisted laparoscopic surgery (HALS) is an alternative extraction option for benign and malignant specimens. The surgeon inserts their hand through a mini-laparotomy incision to facilitate tissue exploration, isolation, and removal. This approach is discussed in detail later in this chapter.

Special Considerations

Although gynecologic surgeons laid the foundations for MIS, concerns about laparoscopy during pregnancy arose due to potential risks to both the mother and fetus. However, extensive research has demonstrated no significant differences between open and minimally invasive approaches in terms of fetal loss, maternal and fetal complications, or premature labor. Therefore, laparoscopic surgery is considered safe and effective for treating surgical diseases at any stage of pregnancy.[21] Several safety precautions should be followed, however. First, pregnant patients undergoing laparoscopic surgery should have an obstetrician involved in their perioperative care. Although fetal heart rate monitoring during the perioperative period is recommended once the fetus is viable, routine use of tocolytics is not. Since laparoscopy is associated with an increased risk of VTE and pregnancy is a hypercoagulable state, sequential compression device use is recommended. Although pharmacologic VTE prophylaxis has not been studied in pregnant patients, unfractionated heparin is safe in pregnancy. It also reduces the risk of VTE in other surgical patient populations. Pregnant patients should be placed in the left lateral recumbent position in the operating room to minimize caval compression and decreased venous return (Fig. 11.16). The abdomen can be safely accessed using either closed- or open-entry techniques; however, entry should be remote to the gravid uterus. Given the risk of a gravid uterus distorting intraabdominal anatomy, some organizations recommend entering the peritoneal cavity under direct visualization (open Hasson technique). Trocars can be placed as usual but with consideration of the fundal height (Fig. 11.17). If fetal distress is noted during insufflation, intraabdominal pressure should be reduced until maternal and fetal vital signs stabilize. Generally, carbon dioxide pneumoperitoneum up to a pressure of 15 mm Hg is deemed safe.[21]

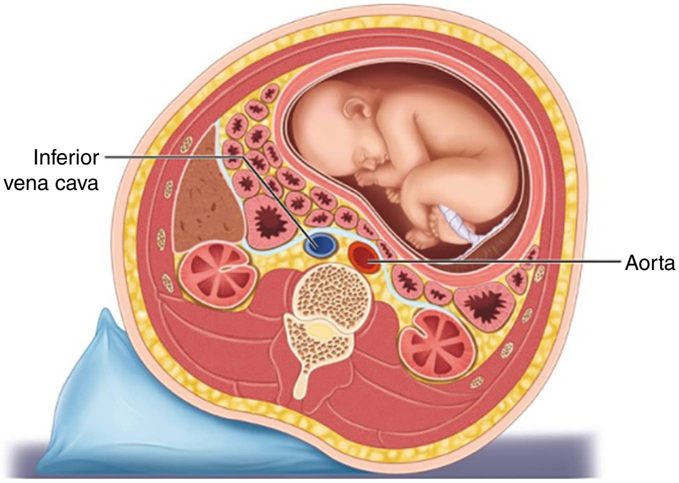

FIGURE 11.16 Pregnant patients are positioned in the left lateral decubitus position during laparoscopic surgery to minimize aortocaval compression, thereby maintaining adequate blood flow and reducing the risk of hypotension. (From Schellenberg M, Polk TM. Trauma and surgical management during pregnancy. In: Nezhat C, Kavic M, Lanzafame R, Lindsay M, Polk T, eds. *Non-Obstetric Surgery During Pregnancy*. Cham: Springer; 2019.)

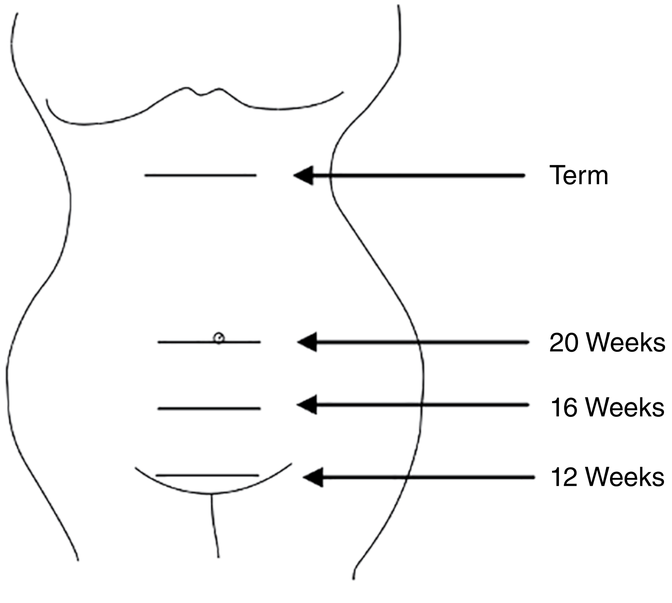
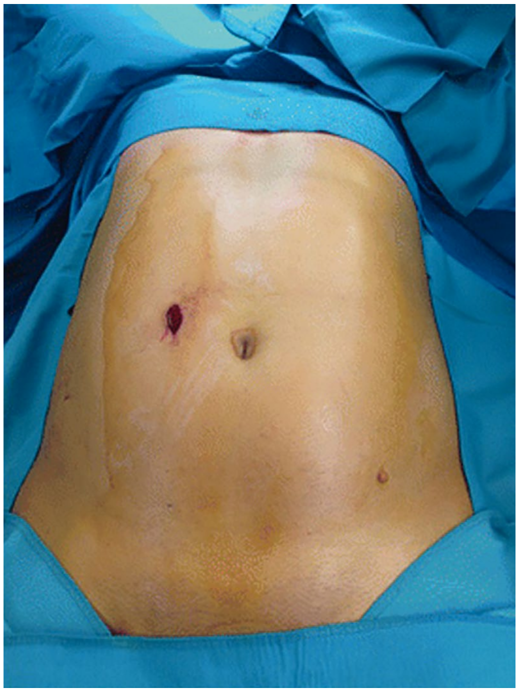
Traditionally, hemodynamically stable trauma patients are managed with serial abdominal examinations and paracenteses to monitor for signs of intraperitoneal bleeding that might necessitate a laparotomy. In this patient population, laparoscopy can aid in diagnosing and treating blunt and penetrating traumatic injuries. However, the increasing use of rapid helical CT and bedside ultrasound has made them primary assessment tools over laparoscopy. Despite its unclear diagnostic role in trauma evaluation algorithms, laparoscopy surpasses CT and ultrasound in detecting penetrating thoracoabdominal trauma and injuries to the diaphragm, hollow organs, and retroperitoneum. Numerous studies have highlighted the value of laparoscopy in blunt and penetrating



SAGES

FIGURE 11.17 The uterus progressively enlarges during pregnancy: at 12 weeks, the uterus is just above the pubic symphysis; at 16 weeks, it is midway between the pubic symphysis and the umbilicus; at 20 weeks, it reaches the level of the umbilicus; and at term, the uterus can extend up to the xiphoid process. (From Mueller CL, Okrainec A. Chapter 14. Laparoscopy during pregnancy. In: Soper N, Scott-Conner C, eds. *The SAGES Manual*. New York: Springer; 2012.)



Veli Ozkan et al.

trauma, such as reduced undetected injuries, shorter hospital stays, faster recovery, and potentially lower costs (although the data are limited).[32] Laparoscopy may be a safer and more attractive alternative to invasive trauma laparotomies; however, laparoscopy is not recommended for patients with unstable hemodynamics, as previously mentioned. Patient preparation and positioning for a trauma exploratory laparoscopy should resemble a traditional trauma exploratory laparotomy to allow for a swift transition to open surgery if needed (Fig. 11.18). Instruments for open surgery must be available in the event of conversion. The abdomen should be assessed systematically to reduce the risk of missed injuries. Ultimately, the seamless integration of laparoscopy into standard trauma management protocols demands experienced surgeons, adequate staffing, and appropriate equipment.[18,32]

Postoperative peritoneal adhesions, which form in the abdomen after abdominopelvic surgery, are a normal response to peritoneal surface injury. Adhesive disease varies in severity and can make laparoscopic surgery in a patient with a history of abdominopelvic surgery either straightforward or impossible. Thus, a comprehensive surgical history and physical examination are crucial in the preoperative setting. It is essential to know the type of operation the patient had previously (as this will indicate potential adhesion locations and impact on the intended surgery) and whether the surgery was performed emergently or associated with complications such as bleeding. Prior incisions should be inspected and assessed for signs of hernia, which may require repair. New incisions should be as far as possible from previous operative sites. Adhesiolysis may be necessary once inside the peritoneal cavity to proceed with the intended operation. Combining blunt and sharp dissection techniques with traction–countertraction can help identify the boundaries of adhesions and intraabdominal organs (Fig. 11.19). An angled-lens laparoscope can also be helpful, whereas electrosurgical tools should be used cautiously. Extensive adhesiolysis remote from the field of interest should be avoided because operating in a reoperative field increases the risk of complications, such as bleeding or visceral injury. Minor bleeding can be controlled with pressure before resorting to clips, ligatures, or electrosurgical devices. Visceral injuries often result from excessive traction or tissue misidentification during adhesiolysis and may require repair (Fig. 11.20). It is vital to prioritize patient safety and consider conversion to an open procedure if extensive adhesive disease is found or complications arise during surgery.[21,33]

Postoperative Care

The initial surge of interest in laparoscopy arose from its potential benefits, including less tissue damage, improved cosmesis, reduced hospital stays, and faster recovery. Many healthcare institutions worldwide have sought to establish standardized surgical care practices to further enhance patient care and minimize expenses. In 1997, Danish colorectal surgeon Henrik Kehlet pioneered the “fast-track surgery” concept for patients undergoing open sigmoid colectomy and demonstrated that reducing surgical stress and modifying conventional practices hastened postoperative recovery and shortened hospital stays. In the early 2000s, European surgeons formed the Enhanced Recovery After Surgery (ERAS) Study Group. They released evidence-based recommendations to improve surgical recovery and reduce complications in patients undergoing colonic surgery. The ERAS approach combines interventions such as preoperative counseling, avoiding mechanical bowel preparation, minimizing preoperative fasting, balanced fluid therapy, laparoscopy and short-acting anesthetic

Elsevier; 2022.)

agents, adequate pain management, and early oral feeding and mobilization. Since then, enhanced recovery protocols (ERPs) have been adopted globally and expanded beyond colorectal surgery (Fig. 11.21). Numerous randomized studies have evaluated the impact of ERPs on elective colorectal surgery outcomes and showed decreased complications, shorter hospital stays, faster postoperative recovery, and reduced mortality. When combined with laparoscopy, ERPs effectively implement key components, such as opioid-sparing analgesia and optimized fluid therapy. Several randomized trials have compared laparoscopic and open colorectal surgery using ERPs. A meta-analysis of these trials demonstrated that laparoscopic surgery reduces hospital length of stay,

postoperative complications, and pain due to decreased surgical stress response.[34] Although laparoscopic surgery may have high up-front costs because of specialized instruments and longer operative times, it may be a viable long-term investment. Savings from shorter hospital stays, fewer readmissions, and fewer complications could balance the high up-front cost. For example, a study comparing the cost-effectiveness of laparoscopic and open surgery for rectal cancer found no significant long-term societal cost differences between the two methods, despite the immediate higher costs associated with laparoscopy.[35] Another study found that the laparoscopic colectomy is associated with decreased healthcare costs and usage during immediate and long-term postoperative periods, compared with the open colectomy.[36] More prospective trials are currently in progress to assess the cost-effectiveness of ERPs, with early data supporting overall value costs.

ADVANCES

This section discusses the most recent advancements in laparoscopic tools and techniques.

Tools

Laparoscopic tools can be classified according to the purpose they serve in surgery, including visualization, dissection, hemostasis, and approximation.

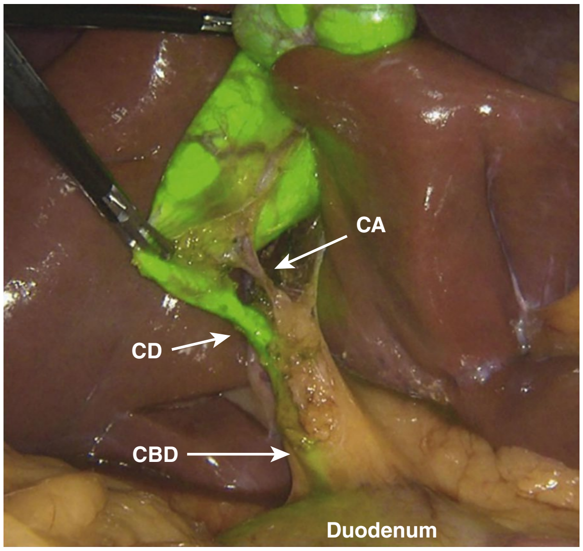
Although superior to direct observation through the narrow tube of a laparoscope, 2D video-laparoscopy is limited by poor depth perception and potentially spatial orientation, which can contribute to surgeon fatigue.[21] In the early 1990s, three-dimensional (3D) laparoscopy was introduced to enhance depth perception, but the technology was not embraced initially (Fig. 11.22). The lack of adoption may have been due to side effects (e.g., ocular fatigue, nausea), poor image resolution, uncomfortable eyewear, and high costs. Newer 3D technology is characterized by high-resolution imaging systems and lightweight eyewear, making it more appealing to modern surgeons. Recent studies evaluating the impact of 3D imaging systems on laparoscopic surgery have shown enhanced depth

FIGURE 11.22 Laparoscope with 3D imaging capabilities. (Courtesy Joshua Roshal, MD.)

perception, spatial resolution, accuracy, surgeon comfort, and operative performance.[37,38] Reduced technical errors and error-related incidents with 3D laparoscopic imaging have been noted as well.[39–41] Three-dimensional imaging may also accelerate the acquisition of laparoscopic skills, as it has been shown to enhance the visualization and execution of complex tasks by surgical trainees.[42] Nonetheless, further research is needed to assess clinically significant patient outcomes and determine the role of 3D vision systems in teaching surgeons advanced laparoscopic skills.

Although advancements in laparoscopic imaging aim to mimic our natural 3D vision, parallel efforts strive to transcend the limits of human visual perception. MIS predominantly relies on the surgeon's observation of tissue illuminated by conventional white-light, light-emitting diode (LED) sources linked to a laparoscope via fiberoptic cables and ambient light in the operating room.

Fluorescence-guided surgery (FGS) has emerged as an innovative imaging approach to enrich the comprehension of anatomy, physiology, and pathology in the operating room. It employs fluorescent substances, light wave frequencies, and imaging systems to improve the distinguishability of various structures and tissue types. For instance, indocyanine green (ICG) is a fluorophore that can be visualized in many tissues of interest. It dissolves in the bloodstream, binds to albumin, and undergoes hepatic metabolism before being excreted in bile. ICG absorbs near-infrared light and emits fluorescence. This fluorescence can be captured by a specialized camera and subsequently superimposed on a white-light image to provide additional insights to the surgeon. For example, ICG can be visualized in the biliary tree to reveal anatomic variations and potentially reduce the risk of common bile duct injury (Fig. 11.23). Two randomized controlled trials have also shown that ICG fluorescence imaging is as effective as intraoperative cholangiography for identifying bile duct variations, which may reduce the risk of bile duct injury.[43] Moreover, ICG can enhance real-time tumor tissue detection, whether at the primary site or in lymph nodes, and sites of metastasis. This visual aid can guide surgeons during cancer surgery to improve safety, curative resectability, and patient survival.[44] Other renally cleared experimental dyes have shown promise in visualizing and identifying the ureters, which is typically challenging in laparoscopic surgery because of diminished tactile feedback and the ureters' retroperitoneal position. Iatrogenic ureteral injury is an infrequent but severe complication of surgery and deserves further study.[43] Finally, FGS can be used to assess the perfusion of bowel anastomoses, and in turn, it has been shown to decrease the incidence of anastomotic leaks compared with traditional visual clinical evaluations of colorectal anastomoses.[45]



Cárdenas et al.

FIGURE 11.23 The critical view of safety during a laparoscopic cholecystectomy, highlighting the cystic artery *(CA)*, cystic duct *(CD)*, and common bile duct *(CBD)* near the duodenum. The structures are clearly identified with fluorescent dye enhancing the visualization to ensure safe dissection and prevent injury to the biliary tree. (From Cárdenas G, Fornaguera I, Díaz del Gobbo R, Ginestà C. Direct gallbladder indocyanine green injection technique to achieve critical view of safety in laparoscopic cholecystectomy. In *Cirugía Española* [English Edition]. 2021; 99[9]:678-682.)

As mentioned, laparoscopic dissection relies on precise tissue separation and effective bleeding control or hemostasis. Hemostasis is crucial for maintaining a clear operative field and avoiding conversion to traditional open procedures. Hence, developing laparoscopic tools that can effectively dissect tissues while ensuring hemostasis is essential. Jacques Rioux, a Canadian gynecologist, introduced bipolar electrosurgery for laparoscopic procedures in the early 1970s.[46] Compared with its monopolar counterpart, bipolar electrosurgery confines the electric current to the active electrodes at the tips of the instrument, offering greater precision and reduced thermal spread that could damage nearby delicate tissues. However, standard bipolar technology can cause sticking, charring, and significant thermal spread when applied to small vessels (1–3 mm diameter). Electrothermal bipolar vessel sealing (EVBS) systems were developed in the late 1990s to enhance bipolar electrosurgical technology and address these limitations. EVBS systems (e.g., LigaSure; Medtronics, Minneapolis, MN) combine an electric current generator and a clamping tool to seal blood vessels up to 7 mm wide by applying controlled electrical energy that heats and denatures the vessel wall to form a secure seal. This technology monitors circuit impedance to prevent vessel wall charring. Upon sealing, the integrated blade safely cuts the vessel. Studies have shown that EVBS reduces intraoperative blood loss and perioperative blood transfusion requirements across various surgical fields.[47]

Harmonic scalpels are an alternative to electrosurgical instruments and harness ultrasonic vibrations instead of direct electric current to coagulate tissues (Fig. 11.24). When an electric current passes through the device's piezoelectric crystal, it generates molecular vibrations that are transmitted to an active blade. The blade vibrates longitudinally against a stationary blade to produce frictional heat that induces tissue coagulation and division.

Laparoscopic surgery has evolved from simple needles and threads to more advanced tools for tissue approximation and reconstruction. Intracorporeal suturing and knot tying are flexible and cost-effective techniques. However, traditional knot tying may soon become outdated as alternatives such as barbed sutures emerge. These knotless sutures have surface barbs that lock tissue in place without knots. Despite their promise of reduced operative time and increased efficiency, further research is necessary to determine their safety and effectiveness. The main obstacle to their widespread adoption is the high production cost, which requires skilled labor and specialized equipment (Fig. 11.25).[48]

Surgical staplers offer another option for approximation, especially for anastomosing hollow organs and ligating ducts or blood vessels. These tools can manually or automatically deploy staples in either linear or circular patterns. Automated staplers have high

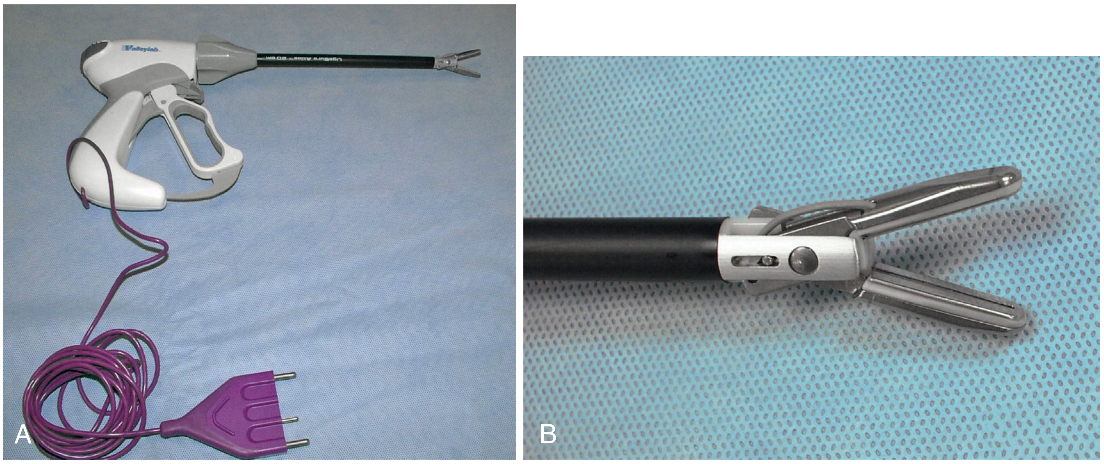


FIGURE 11.24 Vascular sealing device. (A) Hand-held unit. (B) Close-up of sealing tip. (From Mccommon GW. A close view of the gloved hand of a veterinary surgeon cleaning a surgical site with a sterile liquid and gauze sponge. Surgical instruments and aseptic-like technique. costs and learning curves, and concrete evidence supporting their superior efficacy still needs to be demonstrated. Linear staplers are divided into two types, cutting and noncutting. Cutting variants deploy multiple rows of staples on either side of a central blade that divides the tissue linearly, effectively sealing both sides of the hollow lumen. Noncutting devices only deploy staples; tissue division is performed using a separate sharp instrument, such as a scalpel. Currently, noncutting staplers are available for open surgery only. Laparoscopic linear staplers are produced with various handle lengths to accommodate patients with thick abdominal walls, and some feature articulating jaws for angled staple deployment in hard-to-reach areas. Staple height and cartridge length are important considerations when approximating tissues of various thicknesses. An inappropriate staple height may lead to incomplete tissue penetration or malfunctioning staples, which can increase the risk of an anastomotic leak or bleeding. Improper cartridge length may necessitate extra stapler load deployments or leave excess staples in the surgical field. Staples can also be deployed with buttressing materials to reduce the risks of anastomotic leak and bleeding, but evidence supporting their use is inconclusive.[21]

In the quest for "scarless surgery," surgeons are striving to further reduce incision sizes. Most laparoscopic tools can be deployed through 5-mm port incisions; however, some devices, particularly staplers, require 12- to 15-mm port incisions. In 1998, the Canadian surgeon Michel Gagner described a series of 60 laparoscopic cholecystectomies performed with instruments 3 mm in diameter or smaller. This technique, dubbed *needlescopic surgery* or *minilaparoscopy*, showed improved postoperative analgesia and cosmetic results compared with traditional laparoscopic cholecystectomy. Remarkably, one study found that 66% of the incisions were not visible postoperatively.[49] Numerous needlescopic approaches have since been reported for procedures such as appendectomy, Nissen fundoplication, Heller myotomy, splenectomy, adrenalectomy, hernia repair, thyroidectomy, axillary node dissection, colectomy, thoracoscopic surgery, and bedside diagnostic laparoscopy.[50] The most significant limitation of needlescopic surgery relates to the instruments and laparoscopes. For instance, 3-mm laparoscopes offer a reduced field of vision, whereas other instruments are too flexible, fragile, limited, and costly (Fig. 11.26).[51,52] Although

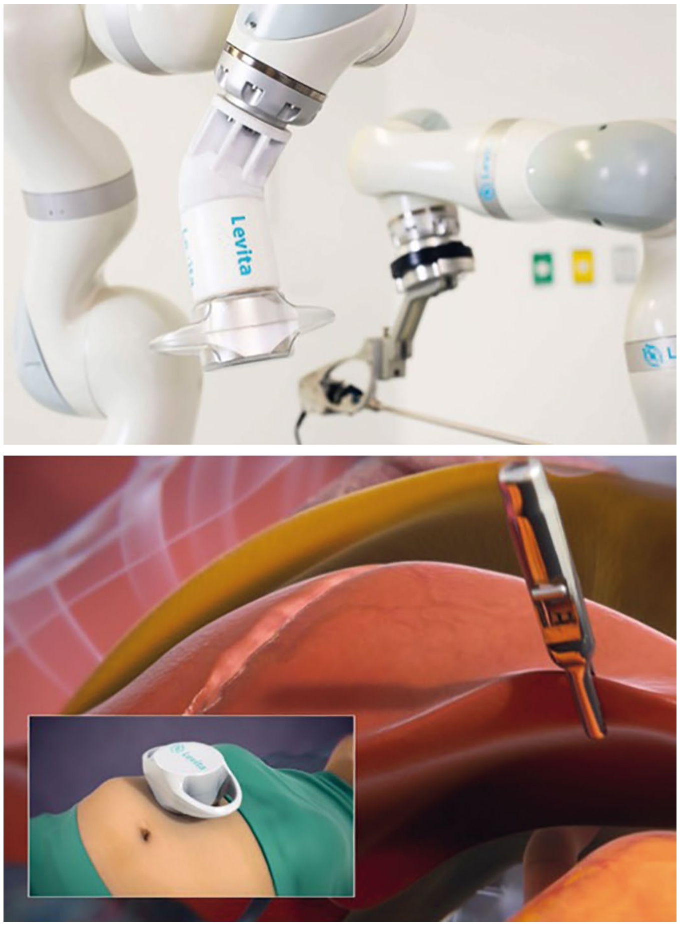
needlescopic surgery appears safe for various procedures, it may also be associated with a prolonged operative time, which may stem from instrument issues.[53] Ultimately, larger studies are necessary to analyze the risks and benefits of needlescopic and laparoscopic surgeries. Needlescopic surgery may ultimately play a beneficial role in a specific set of procedures that avoid the manipulation of heavy organs and anastomoses (e.g., 12-mm stapler required), such as the Nissen fundoplication and Heller myotomy.[54] Although needlescopic surgery has limited applications in adults, the technique is more commonly used in pediatric surgery, given smaller working spaces and viscera.[55]

Although the primary goal of mini-laparoscopy is to reduce incision size, the emergence of magnets in laparoscopic surgery has opened a new path to decreasing the number of incisions made. Magnet-assisted surgery also aims to minimize tissue trauma and enhance cosmesis. The use of magnets in surgical procedures, however, is not recent, with various experimental initiatives evident in GI, biliary, colorectal, urologic, and vascular surgeries. The Levita Magnetic Surgical System, the first magnet-based surgical system to gain FDA approval, consists of a deployable magnetic grasper and an external magnet. These components work together to manipulate the grasper in the peritoneal cavity. In a laparoscopic cholecystectomy, this magnetic grasper can retract the gallbladder to expose the cystic triangle (Fig. 11.27).[56] It can also effectively expose the renal hilum during a robotic pyeloplasty.[57] Although the system seems safe, clinical outcomes research and cost-related analyses are warranted. Beyond retraction, magnets have also been used for tissue dissection, hemostasis, and anastomosis creation. Research into using magnet-assisted surgery to treat conditions such as reflux, back pain, and fecal incontinence is ongoing.[58] Further investigations and clinical trials are required to evaluate the safety, efficacy, cost efficiency, and potential benefits over conventional laparoscopic techniques.

AR systems are being explored as tools to improve vision and reduce cognitive load in laparoscopic surgery.[59] AR overlays digital data onto real-world environments and has proven useful in neurosurgery and orthopedic surgery, where rigid structures facilitate easy alignment between digital augmentation and the actual scene. However, laparoscopic thoracoabdominal surgery is characterized by dynamic anatomy that complicates real-time imaging (e.g., pneumoperitoneum, patient positioning, respiration, instrument motion, organ manipulation) and has led to hesitancy in adopting the technology. Despite these limitations, AR has been successfully used in gynecologic, splenic, hepatobiliary, renal, and adrenal surgeries. By merging preoperative CT or MR images with laparoscopic views, AR can provide



Levita Magnetics

real-time, interactive guidance for surgeons (Fig. 11.28).[60] Though its anatomic precision is imperfect, AR's potential to enhance surgical accuracy and reduce complications is evident.

AI may soon play a role in preoperative planning, intraoperative guidance, and surgical training. As machines that simulate human intelligence, AI is proficient at learning, reasoning, and self-correcting. Machine learning algorithms could be adapted to identify patterns and predict anatomic structures, surgical instrument positions, and procedural steps. Natural language processing could streamline clinical workflows, whereas artificial neural networks may catalyze the acquisition of technical skills. Computer vision, another subset of AI, can potentially analyze intraoperative images and videos to assess the technical competence of trainees.[61–63] The laparoscopic cholecystectomy is a common operation that follows a standardized procedure and provides ample data for exploring machine learning applications. In fact, a computer vision model has been developed to detect and label critical events during a cholecystectomy, demonstrating machine learning's potential to revolutionize surgical practices.[64] However, the use of AI in clinical practice is still relatively limited. As these applications undergo testing in real clinical settings, the primary focus should be enhancing quality and patient safety.

Techniques

Since Mouret's pioneering laparoscopic cholecystectomy, advances in laparoscopic technique continue to be widely shared and discussed on local and global platforms. The following section will concisely overview the theory, applications, and supporting or refuting evidence for specific laparoscopic techniques. We recommend referring to the cited operative manuals for a more comprehensive understanding of the procedural steps.

Laparoscopy, first recognized for its diagnostic potential, has since been optimized for elective and emergency applications. Diagnostic laparoscopy is a valuable tool for assessing acute abdominal pain, peritonitis, sepsis, and thoracoabdominal trauma resulting from blunt or penetrating injuries. Additionally, it can be employed alongside tissue sampling to stage malignancies, diagnose cirrhosis, and determine the etiology of chronic abdominal or pelvic pain (e.g., endometriosis). The procedure typically begins with a periumbilical port incision to facilitate the insertion of a laparoscope. Additional ports may be introduced for adhesiolysis, retraction, palpation, or biopsy purposes. A systematic intraabdominal and pelvic viscera evaluation should ensue, covering the pelvis, midabdomen, right upper quadrant, and left upper quadrant (Fig. 11.29). The positions of the patient and operating table can be adjusted as needed to facilitate organ displacement and visualization.[18]

Suturing and knot tying are essential techniques for hemostasis and approximation. Laparoscopic suturing and knot tying can be challenging given the lengthy instruments, limited mobility, poor tactile feedback, and restricted vision and magnification. Three ports are needed for laparoscopic suturing: an optical port, a needle driver port, and an assisting forceps port. Ideally, the needle driver and assisting forceps ports should be placed at least 7 cm apart and form a 60- to 90-degree angle from the laparoscope's axis (Fig. 11.30). The thread material, needle size, and needle geometry choices should mirror open surgery. Some needles can be introduced into the peritoneal cavity through the ports with either the instrument grasping the needle (with trailing thread) or the thread (with trailing needle). However, large, curved needles may not fit through even a 10-mm port. In these cases, the trocar can be upsized, or the needle can be introduced directly through the skin. There are two knot-tying techniques, extracorporeal and intracorporeal. Extracorporeal knots are tied outside the abdominal cavity and advanced into the operative field using a knot pusher. Intracorporeal knot tying is more complex but preferred for delicate structures because it avoids the seesaw effect and tissue tugging in extracorporeal knot tying (Fig. 11.31). Specific instruments have been developed for intracorporeal suturing and knot tying, such as Medtronic's semiautomatic Endo Stitch device that allows suturing without needing a second instrument to receive the needle after it passes through tissue.[18,21] New laparoscopic suturing devices are constantly being developed, but only a few have become accepted and integrated into surgical practice.

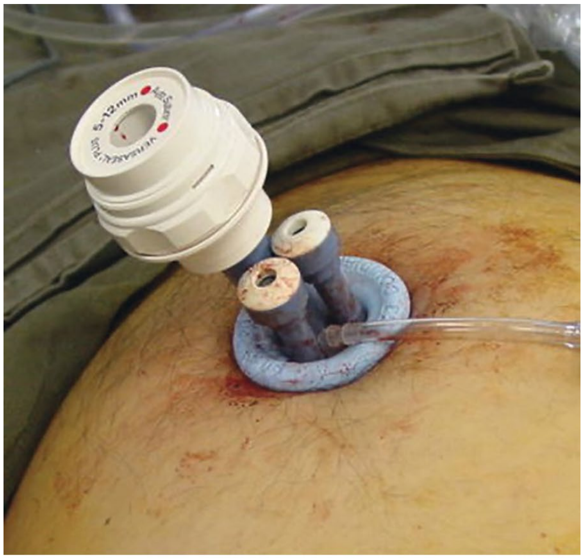
S. H. Emile et al.

FIGURE 11.32 Intestinal anastomosis leak test featuring the peritoneal cavity filled with a saline solution. (From Emile SH, Wexner SD. The reverse leak test for the assessment of low coloanal anastomosis: technical note. *Tech Coloproctol.* 2019;23:491-492.)

Laparoscopic staplers have transformed the landscape of surgical tissue approximation by allowing traditional open procedures, such as a GI anastomosis, to be performed through minimal incisions. These devices are introduced and retrieved via 12- to 15-mm trocars, typically with their jaws closed and unarticulated. The creation of a stapled GI anastomosis begins with target selection. Ischemic or necrotic tissue areas are poor candidates for anastomosis due to the risk of anastomotic leak. Proper tissue compression is also essential. If tissues are not adequately compressed, the staples may not penetrate the tissues correctly or could deform, causing bleeding or a compromised staple line. Some staplers compress tissue as their jaws close, whereas others compress tissue simultaneously as staples are deployed. If the latter device type is used, the staples should be deployed slowly to allow for proper tissue compression, fluid egression, and staple formation to occur. After stapling, the staple line must be evaluated for bleeding and addressed with a clip applier or suture ligature. Occasionally, the staple line may need to be revised with buttress material or smaller staples to achieve hemostasis. Once the staple line is created, the mechanical integrity of the anastomosis can be assessed by submerging the anastomosis in saline and insufflating the bowel with an endoscope or orogastric tube. In this saline leak test, bubbling indicates a flawed anastomosis (Fig. 11.32).[21] Methylene blue, when instilled intraluminally and monitored for extravasation, can also be used to assess anastomotic integrity.[65] Although handsewn anastomoses can be alternatives to failed stapled ones, both methods have similar complication rates.

Single-incision laparoscopic surgery (SILS), also known as *laparoendoscopic single-site surgery*, is an innovative minimally invasive approach through a single incision, typically located at the umbilicus. This incision facilitates the deployment of laparoscopic instruments via a multiport access device (see Fig. 11.29). Though conceptualized over 40 years ago, SILS was only recently adopted. Interest resurged in 1992 in response to a case series detailing single-incision appendectomies. Although the first single-incision cholecystectomy was performed in 1997, early technical challenges hindered the acceptance of SILS. However, laparoscopic cholecystectomies have since become the most researched SILS procedure. Few randomized controlled trials comparing SILS to standard laparoscopic procedures have been conducted, but their results suggest benefits such as improved postoperative analgesia and cosmesis at the expense of longer operative times.[21] In addition, one study found an increased rate of incisional hernia at 12-month follow-up after SILS.[66] The technical limitations of SILS include clashing instruments and the loss of triangulation, given the limited space of a single port. Externally bulky multiport trocars also limit instrument mobility during retraction and dissection. Deflectable-tip laparoscopes, articulating instruments, magnetic anchors, and wireless camera systems aim to address these challenges (Fig. 11.33). Although the aesthetic benefits of SILS may appeal to patients, the primacy of safety and efficacy cannot be overshadowed by mere innovation. Future research endeavors should focus on conducting comprehensive cost-effectiveness evaluations to determine the true value of SILS.

HALS is a hybrid technique combining elements of laparoscopic and open approaches. As discussed earlier, HALS was introduced as a method for extracting large specimens that



Covidien

A case-controlled comparison of single-site access versus conventional three-port laparoscopic appendectomy. *Surg Endosc.* 2011;25:1415-1419; Dickerson JA, Park CW, Pryor AD. Chapter 7. Single-site access surgery. In: Soper N, Scott-Conner C, eds. *The SAGES Manual.* New York: Springer; 2012.)

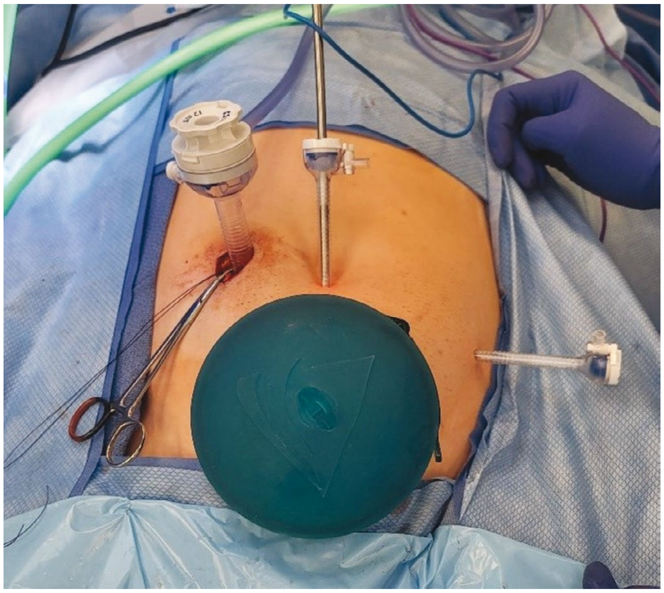

FIGURE 11.34 Hand-assisted laparoscopic total abdominal colectomy. 5-mm umbilical laparoscope port for the camera, 12-mm right working port at the site of the future stoma (this is also the entry site), 5-mm left lateral assistant port, Pfannenstiel incision for hand assist and specimen extraction. (From Park K-T, Jun H, Kim M-G, et al. Simultaneous pancreas-kidney transplantation from living donor using hand-assisted laparoscopic donor surgery: single-center experience. *Transplant Proc.* 2015;47(4):1096-1098.)

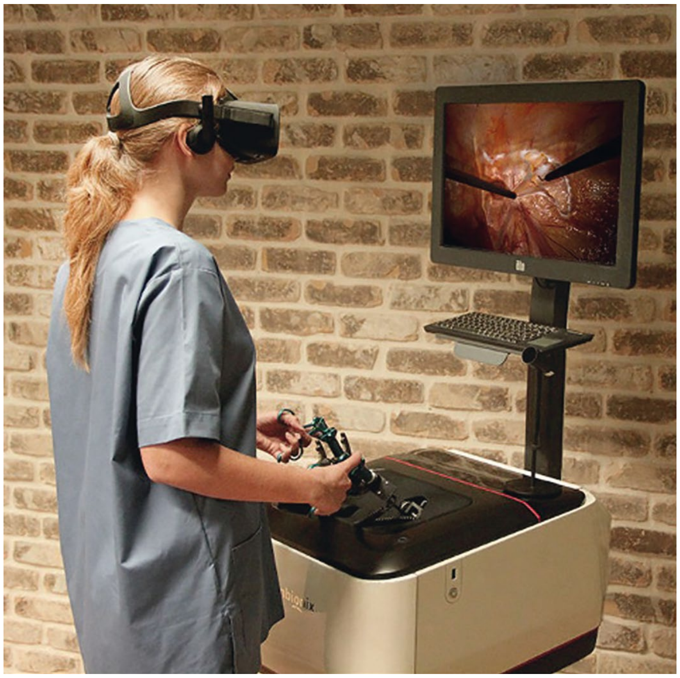
would be unwieldy for small incisions in traditional laparoscopy. In HALS, a sleeve appliance maintains pneumoperitoneum while the surgeon inserts their hand and forearm through a mini-laparotomy incision into the abdomen (Fig. 11.34). The operative field is visualized using a video monitor, with the added benefit of having a human hand in view. This assisting hand enables exposure, traction, palpation, and digital dissection.[21] A significant advantage of HALS is that the surgeon's thumb and forefinger can quickly achieve hemostasis if substantial bleeding occurs during the procedure. In fact, Edward Tiley, an American surgeon, is credited with the first reported use of hand assistance during laparoscopic surgery in 1992 when he used his hand to control bleeding from a gastric vessel during a laparoscopic splenectomy.[67] HALS gained popularity as an intermediate step for surgeons hesitant to adopt pure-laparoscopic approaches due to concerns about steep learning curves, poor tactile feedback, loss of 3D vision, and nonarticulating laparoscopic instruments. Since its introduction, HALS has emerged as a safe and feasible alternative to purely laparoscopic procedures. HALS has been shown to improve depth perception, tactile sensation, and tissue extraction efficiency in laparoscopy. It can reduce operative time and avoid conversion to an open procedure in challenging cases.[68,69] Its relatively shorter learning curve also makes it an attractive option for surgeons transitioning toward minimally invasive procedures or as a training tool. Patient outcomes with HALS are comparable to those of standard laparoscopic or open surgeries in terms of complications, hospital stay duration, and quality of life. However, limitations exist, such as an increased risk of incisional hernia, loss of pneumoperitoneum from hand ports, and decreased visibility given the space occupied by the surgeon's hand. Some of these issues can be mitigated by thoughtful hand port placement (e.g., hand dominance, patient body habitus). Finally, the economic impact of HALS remains debated, with conflicting studies suggesting either increased cost-effectiveness due to reduced operative time and hospital stays or decreased cost-effectiveness because of specialized equipment expenses. Randomized controlled trials are necessary to gain a more thorough understanding of HALS' risks and benefits. Cost analyses should also be conducted to determine the value of hand ports, given their high costs.

TRAINING

Simulation-based education has emerged as a pivotal tool in teaching innovative techniques such as laparoscopy. The age-old paradigm of learning surgery through textbooks and hands-on practice on animals and patients is now challenged by state-of-the-art simulation centers, e-learning platforms, and immersive virtual reality spaces. These contemporary resources, promising enhanced patient outcomes and streamlined competency-based education, have attracted significant funding and support from various surgical organizations. Simulation-based education ensures that trainees master classic procedures. However, as new surgical technologies continue to blur the lines between science fiction and reality, rigorous training remains crucial for trainees and seasoned surgeons alike to ensure quality care and patient safety.

Skills

Simulation-based education is beneficial for both teaching and assessing surgical skills. In 2004, the Society of American Gastrointestinal and Endoscopic Surgeons introduced the FLS curriculum. FLS established a standard set of didactic information and manual skills assessments, serving as a basic curriculum to guide surgical residents, fellows, and practicing surgeons. Mastery of this curriculum was expected to improve the performance, skill, safety, and complication rates in laparoscopic surgery among trainees and practitioners to enhance the quality and safety of surgical care for patients. Recognizing the importance of standardization in training, the ABS made passing FLS a requirement for general surgery certification in 2008, catalyzing innovation in simulation-based training and assessment. Since then, third-party organizations have developed laparoscopic box trainers for trainees to practice independently. Some even offer virtual reality simulations, enabling trainees to refine their technical skills through simulated procedures (Fig. 11.35). Despite evidence demonstrating their utility in improving competency, box trainers suffer from poor trainee utilization.[70] This challenge prompts research on optimal educational content creation, delivery, motivation, and trainee engagement. One potential solution is gamification or incorporating gaming elements such as challenges, feedback, rewards, autonomy, and social interaction into nongaming scenarios. Gamification fosters competition against oneself or others, promotes teamwork and cooperation, and makes educational activities more enjoyable. Aside from physical simulation centers, web-based education platforms have expanded access to quality content. Organizations such as ABS and the American College of Surgeons (ACS) have collaborated to create the Surgical Council on Resident Education (SCORE) curriculum, which is an e-learning platform designed for self-directed learning on diseases and operations. SCORE's structure may evolve as competency-based resident education becomes more prevalent. Another notable platform is WebSurg, which is a free online program specializing in MIS, founded by



Medical Expo

FIGURE 11.35 Commercially available virtual reality simulator for laparoscopic surgery skills training. (From Courtesy Surgical Science.)

Jacques Marescaux, a French surgeon. With over 430,000 members and over 4000 videos available, WebSurg is an international reference for surgical training. Social media platforms like YouTube offer multimedia educational content but lack centralization, standardization, and regulation.

Evaluation and Credentialing

The emergence of MIS prompted further training in advanced techniques. The demand for training led to the development of MIS fellowships in the early 1990s. As fellowship programs expanded, so did exposure to laparoscopy during residency. Though some doubted the continued demand for MIS fellowships, many residents still expressed the need for further training.[13] Today, the primary reason for pursuing an MIS or GI fellowship is to enhance laparoscopic skills or provide more in-depth exposure to specific surgical diseases or procedures.[71,72] The Fellowship Council (FC) oversees several types of advanced GI training programs in North America, including Advanced GI, MIS, Bariatrics, Complex Gastrointestinal Surgery, Comprehensive Flexible Endoscopy, Foregut, and Hepatobiliary (HPB), and has implemented a matching process, standards, and accreditation for these fellowships. FC GI fellowships represent the most prominent postgraduate non –Accreditation Council for Graduate Medical Education training pathway, with over 300 applicants annually and 171 positions across 137 programs, accounting for nearly 25% of all US general surgery residency fellowship applicants. Surgical societies partner with the FC to oversee the educational content of the fellowships. Current sponsoring societies include American Foregut Society (AFS), Americas Hepato-Pancreato-Biliary Association (AHPBA), American Hernia Society (AHS), American Society for Metabolic and Bariatric Surgery (ASMBS), Society for Surgery of the Alimentary Tract (SSAT), and SAGES. Most surgical residents applying to MIS fellowships are members of these societies, which highlights the advantages of mentorship and education programs.[71] Finally, organizations such as the ABS and the American Board of Medical Specialties (ABMS) maintain high educational standards for future surgeons.

The future of education in MIS will likely be defined by the Entrustable Professional Activities (EPA) curriculum outlined by the ABS or through the FC and video-based assessments (VBAs) of technical and nontechnical skills. The impetus for the EPA curriculum is that for generations, case volume and years of training were surrogate measures of competency in surgery. Instead of judging a physician's readiness to practice based on the number of years spent in training, an EPA-based curriculum focuses on the tasks that a physician should be able to perform independently at the end of their training. The FC implemented an EPA-based training paradigm in 2020, and the ABS rolled out an EPA program in July of 2023. These organizations support an EPA-based curriculum and evaluation process because it offers a more practical, real-world approach to assessing surgical competency. By defining a set of tasks that all surgeons should be able to perform, the ABS can better ensure that every certified surgeon has achieved a certain competency standard. Moreover, the EPA curriculum provides a more standardized approach to assessing performance. Under the previous system, surgical trainees might have had different experiences and opportunities, which could result in varied skills and competencies. The EPA model helps to mitigate this issue by specifying a consistent set of tasks and competencies that all trainees must master. In addition, the EPA approach promotes more active learning and focused feedback. Since each EPA represents a critical task that a surgeon should be able to perform, trainees and educators can use them as specific areas for assessment and feedback.

VBAs and coaching have become increasingly popular in competency evaluations.[73] The gold standard of assessing trainees' technical skills in the operating room by staff surgeons is plagued by single-rater variability, patient safety concerns, and pressures to increase efficiency in the operating room. VBAs enable convenient, efficient, and objective evaluations of technical skills and decision-making processes. VBAs are used to review and assess precise movements, procedural steps, and the overall flow of a surgery. Multiple raters can independently observe and analyze a trainee's performance to reduce individual bias. Videos can also provide a means to track progress over time. Regular video assessments can help document improvement and identify persistent areas of difficulty in technical and nontechnical skills development. Furthermore, video assessments can be performed remotely, reducing the need for physical presence and democratizing access to surgical training.[74–76] However, there are challenges associated with this assessment method, including recording, editing, and the legal implications of recording operating room performances. Although further research and cost-benefit analyses are warranted, VBAs may help meet increased assessment demands in an era of competency-based medical education (Fig. 11.36).

American College of Surgeons–Accredited Education Institutes

Currently, simulation education and research are strongly supported by Accredited Education Institutes (AEIs) verified by the ACS. These centers aim to enhance patient safety by using high-fidelity simulators, virtual reality trainers, and realistic models to train surgeons. There are two categories of accreditation for these centers: comprehensive and focused. Comprehensive AEIs have more stringent requirements for learners, facilities, and personnel

Duke University

FIGURE 11.36 A view of an operating room (OR) from an OR Blackbox device. (From Courtesy HuthPhoto for Duke Health.)

than focused AEIs. However, both institutes must meet rigorous accreditation standards and undergo thorough multilevel review processes. Additionally, formal fellowships in surgical simulation and education exist to improve future surgical care by cultivating leaders and scholars in surgical education and simulation. Fellows learn pedagogy theory and gain experience in curriculum development and assessment, simulation center management, education research, and grant writing.

CONCLUSION

In this chapter, we explored the evolution of laparoscopy, transitioning from an era when open surgery was revered as a reflection of anatomic knowledge. Despite initial hesitations, surgeons soon acknowledged the undeniable advantages of minimally invasive approaches. Laparoscopy, now a core tenet of surgical practice, is bolstered by tools and techniques that enhance safety and efficacy. With innovations such as magnetic instruments and AR, surgeons continue to push the limits of what can be achieved through small incisions. The need for responsible application of advanced technologies has prompted increased organizational oversight and a paradigm shift in surgical education. We invest in simulation centers, sophisticated training platforms, and dedicated educators to ensure safe and efficient surgical training. As we look ahead, we expect continued innovation in surgical skills, techniques, and teaching methods. However, as stressed throughout this chapter, we must not embrace technologies solely for their novelty. We must instead assess their potential to enhance surgeon performance, enrich trainee education, and, most importantly, promote patient well-being.

Summary

ENDOSCOPIC TRAINING

Since its inception, surgeons have been at the core of endoscopy, both its use and innovation. Over two centuries ago, in 1806, Dr. Philipp Bozzini developed the *Lichtleiter,* a device using candlelight and angled mirrors to look inside the living human body, which was initially intended for pharyngeal investigation and adapted for peering into the urethra.[1] Though urology can boast developing the first true, working endoscope (the 1878 cystoscope by Dr. Maximilian Carl-Friedrich Nitze and Joseph Leiter[1,2]), general surgeon Dr. Jan Mikulicz-Radecki (who, notably, trained in the surgical clinic of Dr. Theodor Billroth) developed the first gastroscope in 1880 (also assisted by Joseph Leiter).[3] However, it was not until the 1950s, when fiberoptics entered the scene, that surgical endoscopy use began to balloon.[2] Since then, endoscopy has been a core tenet of diagnosing, treating, and surveilling the surgical patient.

The move from diagnostic to therapeutic endoscopy took hold in the 1960s, with the first endoscopic retrograde cholangiopancreatography (ERCP) performed by Dr. William S. McCune in 1968,[4,5] the first colonoscopic electrosurgical snare polypectomy performed by Dr. Hiromi Shinya in 1969,[6] and the first endoscopic management of upper gastrointestinal (GI) hemorrhage performed by Dr. C. Roger Youmans, Jr. in 1969.[7] Subsequently, endoscopic therapies continued to develop and are still the topic of much ongoing innovation today. This high level of innovation in technique also requires innovation in teaching and training the next generation of surgeons and physicians.

The Society of American Gastrointestinal and Endoscopic Surgeons (SAGES) was founded in 1981 by surgical endoscopists who not only understood the benefit of endoscopy in the surgeon's arsenal but also aimed to promote the surgeon's role in performing and *teaching* these procedures.[8,9] Despite the plethora of surgical options, endoscopy still makes up the majority of caseloads among general surgeons nationally, especially in rural areas.[10–13] Appropriately, endoscopy is a required caseload subset for all general surgery residency graduates, per the American Board of Surgery (ABS) and Accreditation Council for Graduate Medical Education (ACGME).[14] A 2006 survey of general surgery program directors in the United States reported a trainee average of 20.2 ± 22 upper endoscopies and 35.5 ± 44 colonoscopies among graduating general surgery residents.[15] In 2009, the number of ABS-required endoscopic cases for graduation increased to 50 colonoscopies and 35 upper endoscopies (previously 29 endoscopies) to align with a prospectively identified competency number of 50 colonoscopies among surgeons, surgical fellows, and surgical residents.[16,17] However, there was (and is) concern that case numbers alone would not equal sufficient training to obtain competency among general surgery graduates. A national survey in 2015 of general surgery residents revealed that only 66.7% of senior residents reported confidence in performing upper endoscopy and 52.7% in colonoscopy.[18] Another national survey in 2016 found that only 29% of responding residents felt comfortable performing advanced endoscopy and only 5% in performing therapeutic endoscopy cases.[19] As such, there have been efforts to enhance the design and efficacy of endoscopic curricula in surgical residency training.[9,14,20]

In 2014, the ABS introduced the ABS Flexible Endoscopy Curriculum for general surgery residents, requiring completion for those graduating in 2017–18 or later. This curriculum complements the endoscopic caseload requirements. It includes five levels of cognitive and technical milestones (to roughly approximate postgraduate year [PGY] level), including resources and scorecards for grading, yet it still permits flexibility for each unique training program (Table 12.1).[21] Graduating residents must score at least an 18 on the Global Assessment of Gastrointestinal Endoscopic Skills (GAGES) Upper Endoscopy and Lower Endoscopy Scoresheets, which include a Likert score of 1 to 5 (5 being best) in five different categories: endoscopic intubation (GAGES Upper Endoscopy only), scope navigation, use of strategies (GAGES Colonoscopy only), ability to keep a clear

TABLE 12.1 **The American Board of Surgery Flexible Endoscopy Curriculum for General Surgery Residents**

LEVEL	PGY	COGNITIVE MILESTONES	TECHNICAL MILESTONES
I	PGY1 or 2	Basic understanding: GI disease and endoscopic anatomy	Basic scope manipulation with simulation or clinical tutorial exposure
II	PGY1 or 2	Basic understanding: endoscopy function	Proper endoscope setup and function; troubleshooting of common problems
III	PGY2 or 3	Indications and contraindications of upper and lower flexible endoscopy, with periprocedural patient management	Tutorial, dedicated endoscopy experience, intraoperative endoscopy, ICU endoscopy
IV	PGY3 or 4	Image differentiation of normal/abnormal pathology, understanding intraoperative and postoperative GI anatomy, appropriate use of endoscopy	Intraoperative endoscopy, ICU endoscopy
V	PGY4 or 5	Tools/adjuncts for therapeutic endoscopy	All skills listed under the ABS description of a surgical endoscopist

ABS, American Board of Surgery; *GI,* gastrointestinal; *ICU,* intensive care unit; *PGY,* postgraduate year.

endoscopic field, instrumentation, and quality of examination. By the end of residency, all graduates are also required to complete and pass the Fundamentals of Endoscopic Surgery (FES) program.

The FES program, developed by SAGES, is composed of a standardized curriculum with online didactics and a validated assessment of knowledge via a multiple-choice test and a virtual reality endoscopic skills assessment.[20] Though now a requirement for board eligibility after graduation from a general surgery residency, the FES program is also available to surgeons-in-practice and other specialties seeking to improve and test their skills. Though minimum endoscopic caseloads are required for all graduating general surgery residents, when there is limited clinical exposure, simulation-based training can improve endoscopic training and increase the likelihood of a candidate passing the FES examination, even at an early stage of training.[22,23] A single-institution study of a simulation-based Endoscopy Training System curriculum yielded a PGY2 FES pass rate of 92% with a mean score of 454, which is similar to the PGY5 residents in the same program (pass rate 89%, mean score 427, $P = 0.3$) and comparable to benchmark data of endoscopists with >300 cases.[21,22] Furthermore, completing all components of the ABS Flexible Endoscopy Curriculum has been strongly associated with passing the FES examination (OR 2.3, 95% CI 1.5–3.7).[24]

Training a competent surgical endoscopist spans beyond residency. For those with career aspirations particularly rooted in minimally invasive techniques and treatment of surgical patients, SAGES developed the SAGES Flexible Endoscopy Course for fellows, which is offered to all first-year minimally invasive surgery (MIS), bariatric, and flexible endoscopy fellows in North America.[25] This 2-day, intensive course consists of case presentations (six 15-minute presentations), expert panels (four 45-minute panels), and labs (eight sessions for 22 different procedures) led by 18 different faculty members. Empiric investigation of this course has shown improvement not only in participant skill (decreased time to perform a targeting task by 40% and decreased error rates by 49%), but also improved fellow confidence and intention to use surgical endoscopy in their future practice.[8] Beyond the official training of residents and fellows, ongoing clinical practice and training in surgical endoscopy is an important part of continuing medical education, especially with evolving techniques and technologies in surgical endoscopy.

PER ORAL ENDOSCOPIC MYOTOMY

Per oral endoscopic myotomy (POEM) is a therapeutic endoscopic technique with origins from the late 1970s[25] and popularized in its current methodology by Dr. Haruhiro Inoue and colleagues in 2008. In their series, POEM was performed in 17 patients with achalasia using a long submucosal tunnel to divide the circular muscles of the gastroesophageal junction (GEJ).[26] Results demonstrated a reduction in dysphagia symptoms score and lower mean resting lower esophageal sphincter (LES) pressure. This initial success with POEM encouraged further innovation and widespread adoption of POEM for the treatment of achalasia and other LES pathologies.

Indications for Per Oral Endoscopic Myotomy

Esophageal achalasia is a relatively uncommon disorder with an incidence of 0.03 to 1.63 per 100,000 persons per year.[27] It is characterized by absent relaxation of the LES and abnormal esophageal peristalsis, creating a functional esophageal outlet obstruction. It is hypothesized to be secondary to the degeneration of inhibitory neurons in the esophageal myenteric plexus due to a chronic inflammatory process and is incurable. Achalasia's etiology is not known but may be due to infection, genetic predisposition, autoimmune conditions, or paraneoplastic syndromes. Common symptoms of achalasia include dysphagia to solids and liquids, regurgitation, chest pain, heartburn due to stasis and fermentation, and weight loss.

Medication, surgery, and endoscopy are the mainstay treatment modalities for achalasia. The goal of these interventions is to reduce symptoms by facilitating esophageal emptying and preventing further esophageal dilation. Oral calcium channel blockers and nitrates induce LES relaxation but require multiple daily dosing and may cause side effects such as headache, hypotension, and pedal edema. Surgical myotomy is a definitive treatment for achalasia and involves disrupting the circular fibers of the LES. Partial fundoplication is recommended after laparoscopic myotomy to prevent reflux after myotomy. In a study done by Campos and colleagues, postoperative gastroesophageal reflux was found in 31.5% of patients without fundoplication versus 8.8% with fundoplication.[28] Finally, endoscopic interventions include Botox injection, pneumatic dilation, and endoscopic myotomy. The POEM procedure has gained traction recently as an efficacious, durable, and safe alternative to surgical myotomy. Werner et al. concluded that POEM was noninferior to surgical myotomy in controlling symptoms of achalasia at 2 years.[29] Esophageal morphology should also be considered before performing POEM because patients with a sigmoid esophagus have up to a two times increased risk of complications.[27]

Expanded indications for POEM include hypercontractility disorders of the esophagus, which can be divided into spastic and nonrelaxing LES disorders. POEM has been successfully performed in patients with diffuse esophageal spasm, hypertensive LES, type III spastic achalasia, nutcracker esophagus, and jackhammer esophagus.[30] Longer esophageal myotomy has been suggested for spastic disorders, such as diffuse esophageal spasm, and may be superior to laparoscopic myotomy because of the ability to extend the myotomy proximally onto the esophagus.

Technique

The technique for POEM was first described by Dr. Haruhiro Inoue but has undergone adaptations with the advent of new technology and experience with this procedure.[26] We will present the authors' current technique in the following section.

After the patient has undergone diagnostic testing for achalasia, and it is determined that they require surgery, they are referred for preadmission testing if needed. Due to the risk of esophageal stasis, we recommend a clear liquid diet for 48 hours before surgery then nil per os starting the midnight before surgery. Accumulation of food debris and liquids in the esophagus at the time of surgery makes intubation and performing the endoscopy more difficult and dangerous. Some endoscopists will initiate pharmacoprophylaxis before the procedure that includes fluconazole 200 mg daily for 3 days before the procedure due to higher rates of esophageal candidiasis in achalasia.

After intubation, the patient is positioned in the supine position with the head directed slightly to the left. The endotracheal tube is secured to the right side of the patient's mouth as the endoscopist stands on the left side of the patient. To facilitate ergonomic positioning, the endoscopy screen should rest at eye level on the patient's right side, located at the level of the chest. We use a high-resolution, single-channel gastroscope with a 2.8-mm working channel as well as an Guardus Overtube (Steris, Dublin, Ireland). Pharmaceutical-grade olive oil is preferred to lubricate the scope because sterile lubricating jelly often desiccates with prolonged endoscopy time. We use a dissecting cap over the tip of the gastroscope to improve visualization and assist with dissection. Zinc oxide pink tape is placed circumferentially around the cap to ensure that it does not dislodge from the gastroscope. We ensure that carbon dioxide is used for insufflation due to the common development of capnothorax, capnomediastinum, and capnoperitoneum during POEM, which resolves more quickly than air accumulation.

On initial endoscopy, retained food or liquid is suctioned completely from the esophagus. For large pieces of food or other debris, it may be necessary to use a large diameter (i.e., 32-French) orogastric lavage tube to facilitate removal. It is best to use an overtube if an evacuation tube is required. Views of the esophagus and stomach are obtained along with retroflexed views to assess for neoplasia or pseudoachalasia. While in the stomach, a spot tattoo is placed 2 cm distal to the GEJ on the anterior surface of the lesser curvature with methylene blue dye to identify the distal extent of myotomy. Starting 3 to 5 cm proximal to the planned myotomy, a saline lift and vertical mucosotomy are performed to access the submucosal plane. A vertical mucosotomy is preferred over horizontal due to the ease of closing the defect with clips. A HybridKnife (Erbe USA, Marietta, GA) or a triangle tip knife (Olympus America, Center Valley, PA) are our preferred sharp dissection devices for electrosurgery. A submucosal tunnel is developed between the mucosa and the circular fibers of the esophagus to the inked gastric submucosal landmark (Fig. 12.1). Periodically injecting 5 to 10 cc of methylene blue-tinted saline to the submucosal space during the dissection is helpful in delineating the muscular and submucosal planes. The gastroscope cap can be deflected to separate the layers and create tension on areolar tissue planes that can then be divided with the knife. Intermittent gastric decompression should be performed because carbon dioxide will distend the gastric lumen during the procedure leading to respiratory changes.

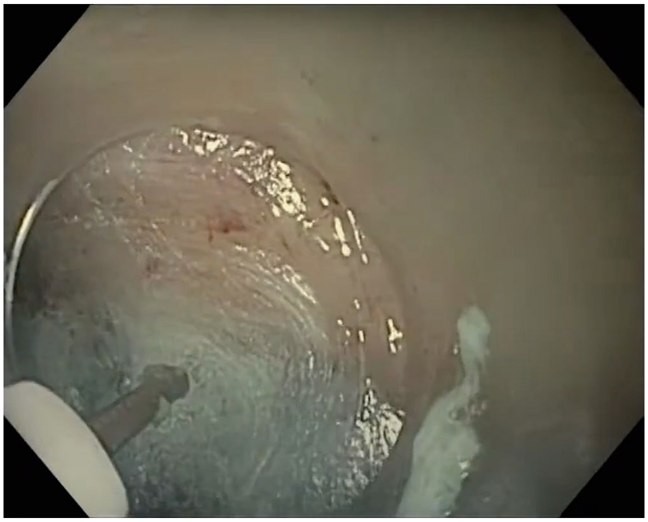

FIGURE 12.1 Creation of the submucosal tunnel with view of the circular muscle fibers of the esophagus.

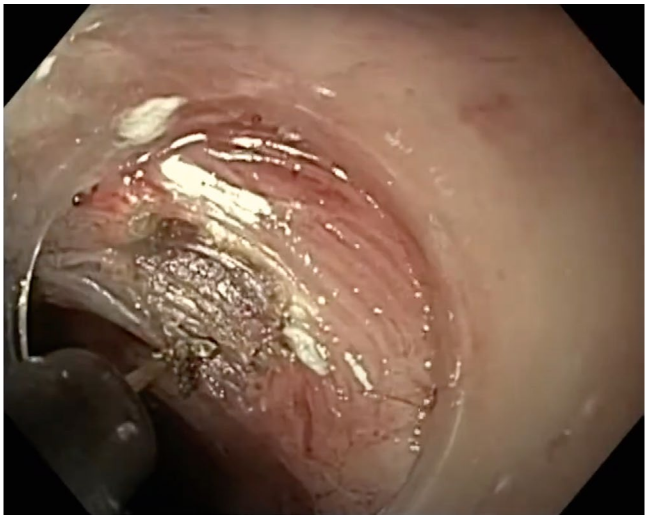

FIGURE 12.2 Myotomy of the circular muscles of the esophagus during per oral endoscopic myotomy.

After the creation of a submucosal tunnel, the circular muscles are divided in a proximal to distal fashion until our submucosal landmark is again identified (Fig. 12.2). The outer, longitudinal fibers should be left intact (Fig. 12.3). At the conclusion of the myotomy, the gastroscope should pass easily into the stomach, and a Hill grade II valve should be apparent. The mucosotomy is then closed with endoscopic clips in the distal to proximal direction. We recommend that the mucosotomy is completely closed to avoid mediastinal contamination. After removal of the overtube, the entire esophagus and stomach is again examined to evaluate for inadvertent mucosal injuries or iatrogenic damage from the overtube.

Postoperatively, a chest x-ray is obtained in the recovery unit to evaluate for capnothorax, capnoperitoneum, or capnomediastinum.

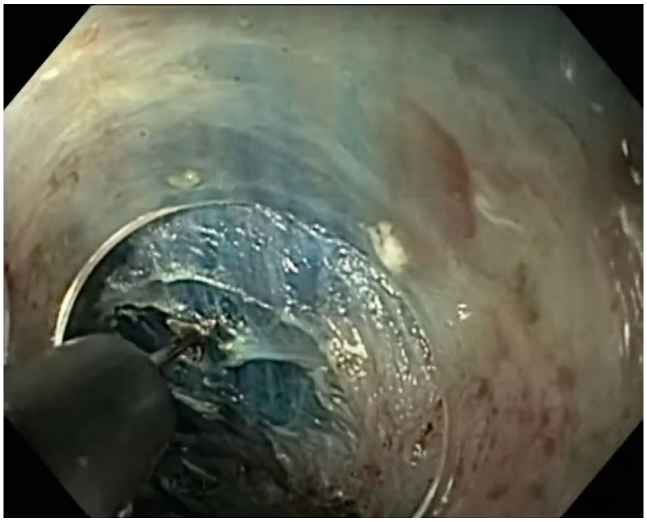

FIGURE 12.3 View of the longitudinal fibers of the esophagus after selective circular muscle myotomy.

Small amounts of peritoneal carbon dioxide can be left alone; however, larger capnoperitoneum can be decompressed using a transabdominal Veress needle or angiocatheter. Similarly, the patient may have small amounts of capnothorax; if there is a large capnothorax that is causing respiratory or cardiac compromise, it may be treated with decompression with catheter/pigtail drain thoracostomy.

The patient is admitted to the floor for overnight observation and kept nil per os. Ice chips can be given for comfort. Our routine is to obtain an upper GI series on postoperative day 1 to assess for leak. If there is no leak, the patient is started on a clear liquid diet and supplemental protein beverages. A puree diet is recommended for 1 week after surgery, and diet is advanced as tolerated. The patient is sent home when they can tolerate a puree diet and oral medication. Most patients will not require opioid pain medication on discharge.

Per Oral Endoscopic Myotomy Follow-Up

Close follow-up after POEM is needed to assess for symptomatic and functional improvement after myotomy. Postoperative surveillance aims to monitor the patient's symptoms, adequacy of myotomy, and esophageal function. Our investigation reveals that nearly 80% of patients with achalasia report clinical success after POEM at 5 years.[31] At the first postoperative visit, an Eckardt score is calculated. The Eckardt score is a summation of four symptoms—dysphagia, regurgitation, chest pain, and weight loss—and is scored 0 to 3 depending on the frequency of symptoms. A score >3 is consistent with the persistence of symptoms or recurrence.[32] During POEM, an antireflux procedure is not performed, so postoperative gastroesophageal reflux is estimated to range from 16% to 22% in large series.[33] Subjective symptoms do not correlate well with postoperative reflux as measured by 24- to 48-hour esophageal pH testing.[10] Therefore, we prefer to perform objective testing that can include timed barium swallow, pH monitoring, upper endoscopy with a compliance planimetry (Endoflip) balloon (Medtronic, Minneapolis, MN), and high-resolution manometry when necessary.

Timed barium swallow has been shown to be a predictor of treatment outcomes in patients with achalasia. Patients who demonstrate a column of contrast >5 cm at 5 minutes should be followed closely because this may indicate treatment failure.[27,34] The pH testing is performed between 6 and 12 months after POEM to assess for pathologic esophageal acid exposure. Finally, we recommend frequent monitoring with esophagogastroduodenoscopy (EGD) due to an increased risk of squamous cell carcinoma in patients with achalasia.[35] EGD is also useful for determining signs of reflux such as esophagitis, stricture, and Barrett esophagus. Compliance planimetry can be performed at the time of EGD to assess the distensibility index of the LES to determine who may require a repeat manometry. High-resolution manometry can assess the completeness of myotomy and evaluate esophageal motility, but it is limited because it does not provide information on bolus retention or reflux. Additionally, it is an invasive procedure. We thus reserve repeat manometry for patients who continue to experience dysphagia after POEM.

Training for Per Oral Endoscopic Myotomy

The ability to perform endoscopic myotomy represents a paradigm shift from the laparoscopic approach in the treatment of achalasia. To ensure safe and effective care with this novel technology, it is imperative to institute a training program that emphasizes the understanding of anatomy and pathophysiology as well as provides hands-on training. Initial didactics should review the indications and workup for achalasia and other motility/hypercontractile disorders of the esophagus. Basic anatomy should be reviewed, paying close attention to the orientation of the muscle fibers of the esophagus, GEJ, and gastric cardia because these serve as valuable landmarks during submucosal tunneling. Trainees need to be familiar with the specific equipment at their disposal to perform the procedure and deal with any intraoperative complications that may arise. Next, teaching sessions should focus on operative technique and understanding the surgical steps needed to accomplish a POEM as well as awareness of common operative complications. Hands-on practice lets the trainee become familiar with the tools available for the completion of POEM. There are several different knives, coagulation instruments, clips, and endoscopic suturing devices that can be used. It is important to gain experience using and manipulating these devices before their use on human patients. After didactic and hands-on training is completed, supervised or proctored cases are needed before achieving competence. For fellows in training, a graduate autonomy approach to POEM is a safe and effective way to learn the procedure.[36] We have found that the learning curve for mastery of POEM plateaus at about 20 cases for experienced endoscopists.[37]

Zenker Diverticulotomy

Zenker diverticulum (ZD) is a false diverticulum located in the hypopharynx in an area of anatomic weakness referred to as the *triangle of Killian* (Fig. 12.4). The triangle is bordered superiorly by the pharyngeal constrictors and inferiorly by the cricopharyngeus. Poor cricopharyngeal relaxation during swallowing causes increased intraluminal pressure and subsequent posterior mucosal and submucosal herniation. ZD is a rare condition with an overall incidence of 0.01% to 0.11% and typically occurs between the fifth and eighth decade of life.[38] Symptoms include dysphagia, which may precipitate weight loss; esophageal borborygmi; regurgitation of undigested food products, which may lead to aspiration pneumonia; and fetor ex ore. Diagnosis is typically obtained with a contrast esophagogram or upper endoscopy, which will reveal an outpouching in the upper esophagus.

The treatment of ZD was historically done via an open left clavicular incision. The goal was to either remove, pexy, or invert

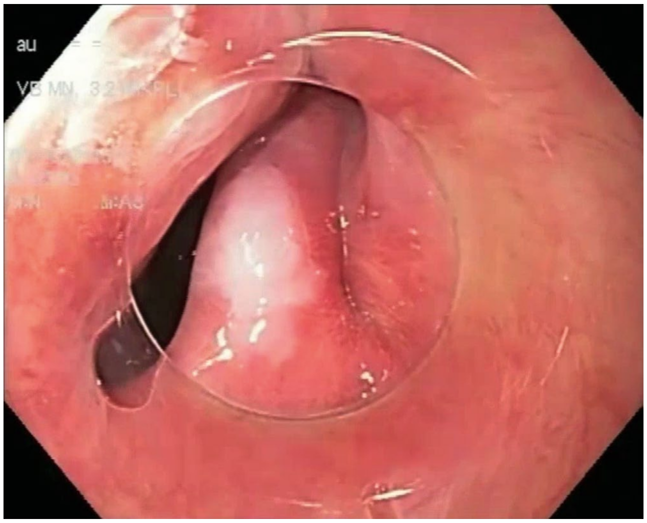

FIGURE 12.4 Endoscopic view of a muscular bar within the esophagus creating a Zenker diverticulum.

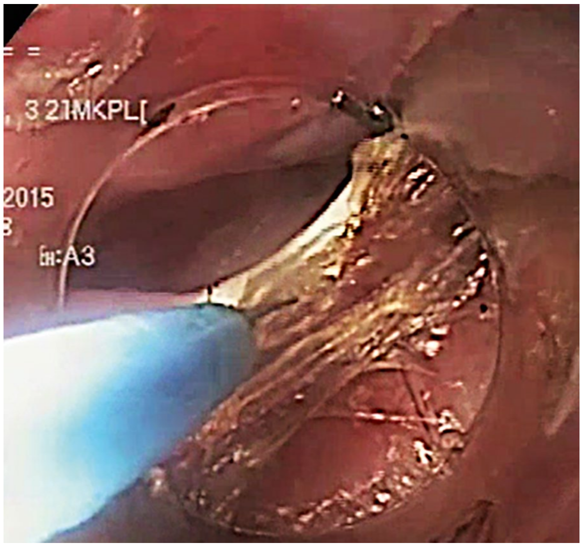

FIGURE 12.5 Myotomy of the cricopharyngeus muscle during Zenker per oral endoscopic myotomy.

the diverticula while performing a myotomy through the cricopharyngeus muscle. Complications from this open approach included vocal cord paralysis, esophageal leak, and mediastinitis. Contemporary management evolved to using a rigid endoscope to divide the common wall of the diverticula and esophagus with staples, carbon dioxide laser therapy, or an ultrasonic scalpel. This approach has several limitations, mainly difficult visualization for overweight patients and those with a short neck. Additionally, it is difficult to identify and divide the common wall of small diverticula.

Flexible endoscopic techniques are becoming popular for the treatment of ZD due to their minimally invasive approach and high success rates. Jain and colleagues found a technical success rate of 99.4% and an overall clinical success rate of 87.9% in patients undergoing endoscopic diverticulotomy.[39]

In the technique, 3 to 5 cc of saline and methylene blue solution is injected into the submucosal space approximately 1 to 2 cm from the apex of the septum, and a short submucosal tunnel is created using the endoscope with a cap and HybridKife (Erbe, Marietta, Georgia). Direct mucosotomy without initial saline lift is an alternative option. As with POEM, carbon dioxide is used for insufflation because of its rapid absorption by the body. The submucosal tunnel is continued along the length of both sides of the septum until the circular and longitudinal muscular fibers of the esophagus are encountered. Saline and methylene blue solution is periodically injected to improve visualization of the muscular and submucosal layers. A myotomy is created over the entire length of the cricopharyngeus muscle in the proximal to distal direction using the HybridKife (Fig. 12.5). Hemostasis is confirmed, and the mucosotomy is then closed via endoscopic suturing or clips. Postoperatively, we keep the patient nil per os overnight; then we obtain a contrast esophagram on postoperative day 1. If there is no leak or obstruction, we initiate a liquid diet and then advance to a soft diet for 2 weeks.

Retrospective studies demonstrate less morbidity and shorter length of stay with similar rates of technical success with Zenker per oral endoscopic myotomy (Z-POEM) versus an open approach, with bleeding and perforation being the most common complications.[39,40] Z-POEM is most likely to have clinical success for diverticula with a septum between 2.5 and 5 cm.[41] In patients with small diverticula, cricopharyngeal myotomy is more difficult, thus predisposing the patient to recurrence. Alternatively, for large diverticula (>5 cm), leaving a residual diverticular sac is a common pitfall that may contribute to recurrent symptoms.[42]

Per Oral Pyloromyotomy

Shortly after Dr. Haruhiro Inouye introduced the first human POEM in 2008, gastric per oral pyloromyotomy (POP), also known as gastric POEM (G-POEM), was successfully completed in 2013 by Dr. Mouen Khashab in a patient with gastroparesis. POP provided a moderate improvement in symptoms due to gastroparesis using an incisionless technique with low complication rates.[43] Gastroparesis is a disorder of delayed gastric emptying without mechanical obstruction and presents with symptoms of nausea, emesis, early satiety, and bloating. The causes of gastroparesis are numerous and poorly understood. Idiopathic gastroparesis is the most common cause, but this condition may also be secondary to diabetes or postsurgical changes. These patients may also have global intestinal transit issues that present with constipation and colonic inertia. Initial treatment for gastroparesis includes prokinetic medications, antinausea agents, and dietary modifications such as several small meals per day and reducing dietary fat and fiber.

If gastroparesis is expected, an upper endoscopy is first performed to determine whether there is a mechanical cause of obstruction, such as malignancy or ulceration leading to the patient's symptoms. A gastric emptying scintigraphy study is highly sensitive in detecting gastroparesis. In this study, prokinetics are held for at least 48 hours, after which the patient is given a sulfur colloid–labeled solid meal consisting of scrambled eggs, bread, and water. Radioactivity is then measured at 1 hour, 2 hours, and 4 hours after ingestion. Normal emptying demonstrates 37% to 90% of the food remaining at 1 hour, 30% to 60% remaining at 2 hours, and 0% to 10% remaining at 4 hours. Greater than 60% retention at 2 hours or >10% retention at 4 hours is indicative of gastroparesis.[44]

POP is performed in the operating room or endoscopy suite under general anesthesia using carbon dioxide for insufflation. The patient is placed supine with the head slightly tilted to the left with a bite block in place. A diagnostic endoscopy is performed by inflating the stomach. A submucosal injection of methylene blue dye is performed about 2 cm proximal to the pylorus. One milliliter of methylene blue dye can be injected submucosally just distal to the pylorus on the greater curvature side to act as a target for the distal extent of the myotomy. At the proximal submucosal injection we use a HybridKife to make a mucosotomy large enough to accommodate the endoscope. A combination of blunt dissection with the capped endoscope as well as sharp dissection with the HybridKife is used to dissect in the proximal to distal direction toward the pylorus. The duodenal muscle fibers will appear perpendicular to the endoscope, which will also indicate the distal extent of dissection. The pylorus is then completely divided with the HybridKife (Fig. 12.6), making sure that all of the circular muscle fibers of the pylorus are cut to prevent recurrent symptoms. The adequacy of myotomy is confirmed by removing the endoscope from the submucosal tunnel and confirming scope passage through an oval-shaped pylorus (Fig. 12.7). The mucosotomy is then closed with clips to reapproximate the mucosal edges. Any inadvertent mucosal injury is identified and clipped.

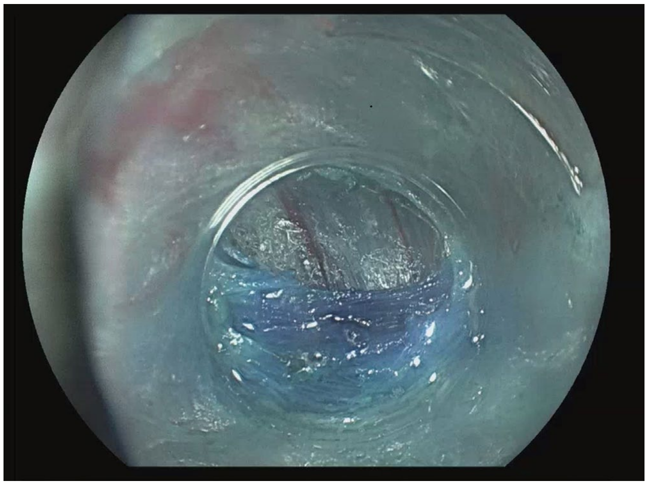

FIGURE 12.6 Endoscopic submucosal view of the pylorus muscle fibers during gastric per oral endoscopic myotomy.

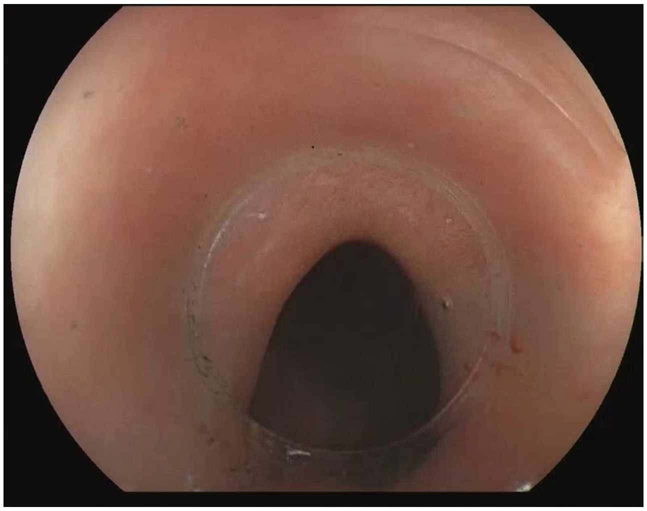

FIGURE 12.7 Intraluminal view of the open pylorus after gastric per oral endoscopic myotomy.

Postoperatively, it is not uncommon for gastroparesis symptoms to transiently worsen due to edema associated with the procedure, but this should improve in subsequent days. Among the authors, practice is split between same-day discharge versus an overnight stay, which includes an esophagram on postoperative day 1 to assess for leak or obstruction. A full liquid diet is started and continued for 1 to 2 weeks. Afterward, soft foods are slowly introduced into the diet. A proton pump inhibitor is continued for at least 4 weeks postoperatively to protect the mucosal closure.

POP has been shown to be a safe and effective alternative to laparoscopic pyloroplasty in the treatment of gastroparesis. One meta-analysis by Mohan and colleagues revealed a clinical success rate of 85.1% after POP versus 84% in surgical pyloroplasty ($P = 0.91$) based on 4-hour gastric emptying scintigraphy.[45] Surgical pyloroplasty is associated with increased length of stay, operative time, and blood loss compared with POP.[46] POP can also be used in postesophagectomy patients who did not undergo pyloroplasty at their index operation. Given its relatively recent popularity, however, additional prospective and randomized studies are needed to understand the true benefits of POP.

ENDOSCOPIC MUCOSAL RESECTION

In the 1990s, endoscopic screening turned to endoscopic treatment of early-stage cancers, such as endoscopic mucosal resection (EMR) and endoscopic submucosal dissection (ESD) for treatment of nonpedunculated lesions to reduce the morbidity of surgical resections.[47] Both techniques were developed for the treatment of nonpedunculated lesions versus en bloc snare resection alone to reduce the risk of full-thickness injury or perforation. These techniques can be used for superficial esophageal cancer, Barrett esophagus, early-stage gastric cancer, some duodenal lesions and cancers, and colon and rectal polyps and cancers.[47,48]

EMR uses a variety of suction, lift, and underwater techniques, usually removing large lesions in a piecemeal fashion when necessary and taking some of the submucosa itself.[47,49] As such, endoscopy and endoscopic ultrasound (EUS) are necessary before a planned EMR procedure to determine whether the lesion is a candidate for resection. Contraindications to EMR for a given lesion include penetration into the submucosa or deeper, size of greater than one-third the circumference of the lumen or lesion size >3 cm, or if the risk of perforation is too high.[49] For lesions amenable to EMR, a surgeon must first undertake an appropriate informed consent conversation, which specifically discusses the risks of EMR over standard polypectomy, with the patient or legal decision-maker. These procedures should be performed only by experienced surgical endoscopists, and only in tertiary care centers, with available multidisciplinary colleagues for support in the unfortunate event of a complication, including diagnostic and interventional radiology and surgery.

EMR should be performed in an endoscopy suite equipped with electrosurgical generators. Insufflation with carbon dioxide is preferred over air because the use of carbon dioxide provides superior patient comfort and decreases readmissions after endoscopy.[50] Colloid solution should be available for submucosal injections as needed because randomized double-blind investigation has shown succinylated gelatin to be superior to normal saline for endoscopic resections by reducing the procedure duration and number of required piecemeal resections of a given lesion.[51] Dye should be available to mark the lesion if unresectable or to mark the resection bed after resection to target subsequent surveillance and treatment if necessary. Snares must be available for piecemeal resections. Due to the risk of bleeding, epinephrine should be at hand, along with coagulation devices and clips.[52,53]

Before resection, the lesion should be viewed with high-definition white light and chromoendoscopy to identify possible submucosal invasion. For colorectal lesions, Paris classification should be assessed because flat lesions with central depression (classification 0–IIa+c) are associated with a higher risk of submucosal invasion.[54] The endoscopist should then ensure an unobscured working view of the lesion, with a straight, relaxed endoscope, with the lesion positioned at 6 o'clock with gravity pulling any intraluminal fluid away from the lesion. If piecemeal resection is necessary, the specimens should include 2- to 3-mm margins of normal mucosa, starting at an edge and working in to reduce the risk of adenoma islands, and using injections as needed to lift the tissue into the lumen and facilitate snare resections.[29] If possible, en bloc snare excisions for lesions 20 to 25 mm are preferred because en bloc resection is associated with lower recurrence rates than piecemeal extraction, when possible, but this must be weighed by the endoscopist against the risk of full-thickness injury or perforation.[55] The endoscopist should ensure that the lesion is removed in its entirety via snare excision and avoid the use of argon plasma coagulation (APC) to treat visible lesions because residual lesions treated by ablation are associated with a higher risk of recurrence compared with complete resection.[54,56] After resection, the defect should be irrigated to ensure that no adenoma islands have been left behind, that hemostasis is achieved, and that there is no evidence of full-thickness injury or perforation.

In the event of a complication, it is important to be prepared. Up to 11% of patients undergoing EMR have intraprocedural bleeding.[57] This can often safely be managed with snare-tip soft anticoagulation.[58] Alternatively, a coagulation grasper or, depending on the location of the bleeding, an endoscopic clip can be used. Up to 7% of patients will present with postprocedure bleeding, often within the first 48 hours, and most improve with supportive, noninterventional care. However, reintervention is indicated for hemodynamically unstable patients or for those who do not resolve with support alone.[57] In these cases, repeat endoscopy should be considered with treatment of any bleeding. If there is no active bleeding, prophylactic coagulation of nonbleeding visible vessels and/or clip closure of the defect from the EMR site have been described as successful possible options.[59,60] In the event of continued bleeding, despite repeat endoscopy, evaluation for surgical resection should be considered. Though interventional radiology to target bleeding vessels can be an option, this carries the risk of subsequent hollow viscus ischemia and associated complications. In the event of perforation, which occurs in 1% to 2% of EMR patients, this can often be managed with clips or endoscopic suturing, pending the size of the perforation and the quality of the surrounding tissue. Some cases of perforation do require surgical intervention. It is important to note that thermal injury from electrical current used during dissection or in hemostasis can present as delayed perforation up to 1 week later.

After EMR, local recurrence rates for colon and rectal adenomas have been described to range from 10% to 30%.[55,56] As such, patients require endoscopic evaluation after EMR resection of adenomas. The first should occur 5 to 6 months after the initial resection, with additional surveillance 12 months later, and it does not require routine biopsies of normal-appearing scar.[48] For patients with Barrett esophagus and high-grade dysplasia, per a 2017 systematic review and pooled analysis, EMR with radiofrequency ablation (RFA) is associated with a 2.6% recurrence rate of high-grade dysplasia, and complete EMR is associated with a 3.3% recurrence rate of dysplasia.[61] As such, after EMR (±RFA), Barrett esophagus patients require endoscopic evaluation within 1 year. Given the morbidity associated with esophagectomy (as the alternative treatment for Barrett esophagus), the American Gastroenterological Association (AGA) recommends endoscopic treatment of Barrett esophagus over esophagectomy, even for high-grade dysplasia.[62] Given these success rates, EMR offers both financial and clinical benefits compared with surgery[63]; however, it requires appropriate informed consent and patient selection, along with appropriately skilled endoscopists and available resources for the initial procedure and subsequent screening and treatment.

ENDOSCOPIC SUBMUCOSAL DISSECTION

ESD was initially developed for gastric lesions with thicker mucosa and involves a very precise injection of gel or fluid into the submucosal layer to lift the entire lesion and facilitate resection (in one specimen) while decreasing the risk of perforation (with perforation rates of ESD described around 2%–3%).[47,64] It has now been described for the treatment of superficial esophageal cancer, Barret esophagus, early-stage gastric cancer, and colonic lesions, along with some use in the duodenum (though more limited given its thin wall).[47] These procedures should be performed by advanced surgical endoscopists at hospitals and health centers with available ancillary staff, including surgery and interventional radiology.

Many of the principles for the technique of ESD are similar to the techniques for EMR noted previously, including initial evaluation with EGD and EUS to confirm the depth of invasion of the disease and appropriate informed consent before the undertaking of ESD for an eligible lesion. Appropriate equipment should be available for the procedure itself and for managing any complications that may arise at the time of the procedure. ESD should be considered for bulkier esophageal or gastric tumors, though it should be limited to lesions less than or equal to two-thirds of the esophageal lumen (Fig. 12.8).[47,64] A submucosal injection is performed to lift the mucosa and a mucosotomy performed (Fig. 12.9A). A submucosal dissection is then performed where the mass is lifted away from the submucosa (Fig. 12.9B) to leave a mucosal defect after the resection is completed (Fig. 12.9C).

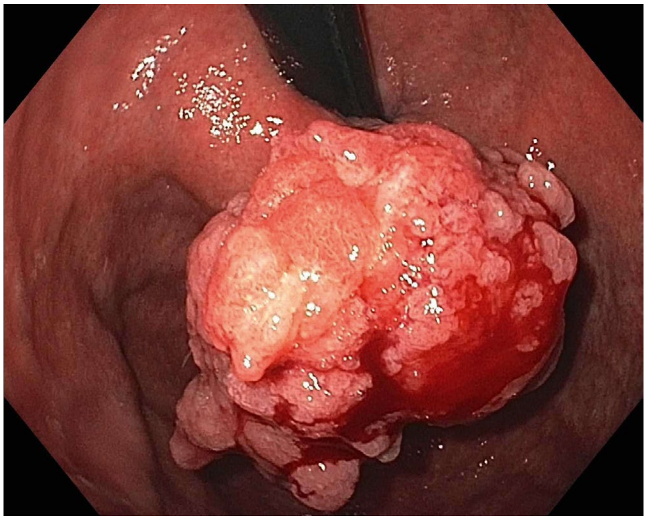

FIGURE 12.8 Endoscopic view of a pedunculated gastric mass.

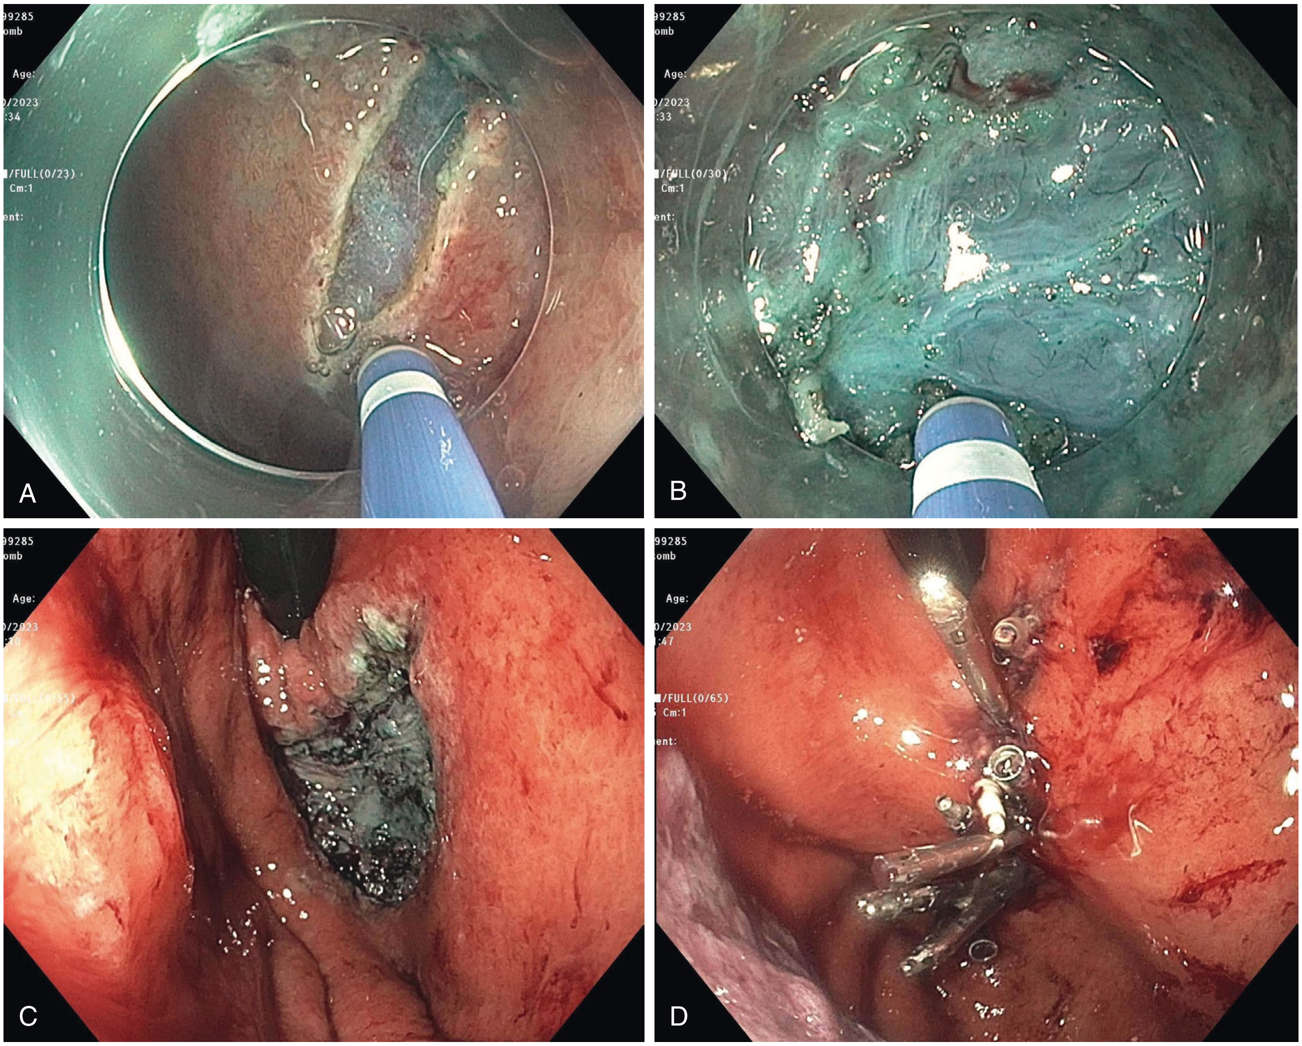

FIGURE 12.9 (A) Gastric mucosotomy performed after submucosal injection for endoscopic submucosal dissection. (B) Submucosal dissection of a gastric mass. (C) Endoscopic view after endoscopic submucosal dissection and removal of the mass. (D) Endoscopic closure of the resection bed.

The mucosal defect is then closed using clips or endoscopic suturing devices (Fig. 12.9D).

ESD can also be considered for duodenal lesions, with success rates of complete resection for nonampullary tumors ranging from 70% to 95%. However, there is a higher risk for perforation, given the thin wall of the duodenum.[47] In fact, the AGA strongly recommends that endoscopists in the United States "refrain from performing duodenal endoscopic submucosal dissection during the early phase of their endoscopic submucosal dissection practice."[65] The benefit of ESD (over EMR), when appropriate, is that there is a better chance of en bloc resection, and recurrence rates are described to be lower (1%); however, procedure time is longer.[66] After ESD, the surgeon should affix ESD specimens to a flat surface and immerse them in formalin for an expert pathologist to evaluate for any margin involvement and depth of submucosal invasion.

After ESD for early gastric cancer, high survival (and low recurrence) rates, even for elderly patients with multiple comorbidities, have been observed: 91.2% overall at 3 years and 54.5% overall, 10-year survival (along with 99.7% 3-year, cancer-related and 97.5% 10-year, cancer-related survival).[67] Furthermore, ESD offers a less invasive approach to management of early gastric cancer than surgical resection, improving the quality of life of many patients.[68] For esophageal cancers, ESD is similarly associated with high survival rates (98%–100% 5-year, cause-specific survival and 85%–95% 5-year, overall survival) and improved quality of life compared with esophagectomy.[69] It should be noted, however, that for patients with incomplete resection after ESD, they may require repeat endoscopic intervention or surgical resection, pending lesion characteristics. These additional therapies may be too invasive for older patients or those with severe comorbidities, and these risks should be thoroughly discussed with patients before attempted ESD.

Regarding training for surgeons and endoscopists to perform EMR and ESD safely and effectively, the AGA recommends a stepwise approach.[65] This should begin with didactic self-study, using available online and text resources. The interested trainee or endoscopist should attend training courses that increase in complexity, such as the SAGES Flexible Endoscopy Course for fellows, with practice on simulation and animal models. For the initial live patient cases, the endoscopist should be proctored by an expert senior colleague, both for assistance in the case of emergency or complication and to be available for technique teaching and improvement. The endoscopist should, of course, begin with cases of low technical complexity and clear indications for endoscopic resection before practice expansion to more complex lesions.

Although EMR and ESD are appropriate for neoplasms that affect the mucosa or subepithelial layers with minimal involvement of the muscularis propria, deeper neoplasms may require a more extensive endoscopic resection. Submucosal tunneled endoscopic resection (STER) and endoscopic full-thickness resection techniques are for highly skilled advanced endoscopists because these involve either near-full thickness (STER) or full-thickness resection of the GI tract.[70]

ENDOSCOPIC MANAGEMENT OF GASTROINTESTINAL TRACT DEFECTS

GI tract defects such as perforations and anastomotic leaks have long plagued surgeons and patients. Although the full suite of options for the management of such defects is covered elsewhere in this textbook, endoscopic management has been growing as a less invasive approach to treatment compared with traditional open or minimally invasive operations. The evolution of endoscopic tools such as stents, through-the-scope (TTS) and over-the-scope (OTS) clips, and suturing devices and techniques has expanded the armamentarium of the endoscopic surgeon and shifted the management of stable patients with GI tract defects to endoscopic approaches.

Endoscopic Stents

For mid to distal esophageal defects, esophageal stenting may be an option for management. Esophageal stents are available as uncovered, partially covered, and fully covered options; however, for the management of esophageal perforations in which the goal of stenting is temporary with the goal of restoring luminal integrity and continuity, fully covered stents (FCS) are the best option because they allow for easy removal. FCS do not have exposed metal in apposition to the mucosa; instead, they are covered with polymeric coating to prevent tissue ingrowth and allow for easier removal.[71] Although this prevents tissue ingrowth into the stent, it also increases the risk of stent migration. As such, for FCS, there should be consideration of clipping or suturing the stent into place.[72] Other complications of stent placement include bleeding, perforation, and a long-term risk of stricture. Additionally, patients may note a foreign body or globus sensation while the stent is in place. For stents placed in the distal esophagus and into the stomach, there is an increased risk of reflux with a resultant impact on quality of life. Though stents with antireflux barriers have been developed, randomized controlled trials of the devices have demonstrated no significant difference in reflux-related symptoms.[73]

Lumen-apposing metal stents (LAMS) are FCS that are designed with a barbell-like design to their flanges. These are generally shorter than traditional esophageal stents with lengths ranging from 8 to 30 mm. First designed for pancreatic pseudocysts to facilitate pseudocyst drainage and endoscopic necrosectomy, uses of LAMS have expanded to include the management of anastomotic strictures and leaks and to facilitate endoscopic anastomoses, such as gastrojejunostomy and cholecystoduodenostomy. Risks of LAMS placement include bleeding, perforation, dislodgement with a subsequent leak, inappropriate placement (if placed under EUS guidance), and stent migration. Ongoing studies are underway and should be evaluated to determine the safety and efficacy of such techniques before widespread adoption or replacement of current surgical approaches. However, in some patients, particularly those who are inoperable, endoscopic stents may be the optimal option to minimize surgical risks.

ENDOLUMINAL VACUUM-ASSISTED CLOSURE THERAPY

For large, contained GI tract defects, endoluminal vacuum-assisted closure (EVAC) therapy has been demonstrated as a safe and effective technique to speed the collapse and granulation of large abscess cavities and promote closure of GI tract defects. First reported in the literature in 2008 to manage a rectal leak,[74] it has since been reported in management of leaks of the esophagus, stomach, small bowel, and colon. In Europe, there are commercially available VAC devices that combine a sponge with a suction tube to promote negative-pressure wound therapy (NPWT). In North America, however, there are no commercially available devices. As such, clinicians have resorted to off-label use of existing NPWT supplies.

After a leak has been clinically identified via axial imaging or fluoroscopy, the patient's stability must first be assessed. For unstable patients with sepsis, appropriate resuscitation should be performed, and consideration for operative intervention should be made. While some data have suggested that endoscopic therapy can be utilized for unstable patients, this is not definitive and should be reserved for specialized centers with surgeons and endoscopists experienced in such management.[75] For stable patients who are within 90 days of developing a leak, EVAC therapy should be considered, either alone or in combination with other endoscopic interventions such as stenting or clipping/suturing. Patients experiencing a leak over 90 days have a lower likelihood of having effective endoscopic closure of their leak.

For patients who may benefit from endoscopic therapy, endoscopic evaluation of the GI tract defect is first performed, typically under fluoroscopy, to facilitate identification and characterization of the defect and its extent. The size of the cavity to be closed should be estimated through a combination of endoscopic and radiographic measurements. A black sponge is then fashioned around a 16-French nasogastric tube. We use a 0 polypropylene suture to secure the sponge to the nasogastric tube through one of the side holes. We then tie an air knot off the tip of the tube to use as a handle to help endoscopically pull the sponge into the esophagus or the colon, through the defect in the GI tract, and into the abscess cavity. For defects of the upper GI tract, the nasogastric tube must first be introduced through the nares and out of the mouth before the sponge is secured to the nasogastric tube. Petroleum gauze dressing can be used to cover the parts of the sponge that may come into contact with mucosa; however, this is not absolutely necessary because some endoscopists will place a sponge within the lumen of the GI tract to facilitate closure of small defects (Fig. 12.10).

It is important that the negative-pressure therapy not exceed 125 mm Hg suction. Furthermore, the EVAC sponge should be exchanged every 3 to 4 days as NPWT will promote granulation of the cavity that can grow into the sponge. During exchange of the sponge, the endoscope should be used to push the sponge away from the wall of the abscess cavity to help free the sponge from granulation tissue. Endoscopic injection of oral contrast under fluoroscopy can help to demonstrate a reduction in size of the cavity. If no progress is made in 2 weeks, the patient should be reassessed for alternative approaches, such as surgery.

The effects of EVAC therapy leading to closure are hypothesized to occur as a result of four mechanisms. With macrodeformation,

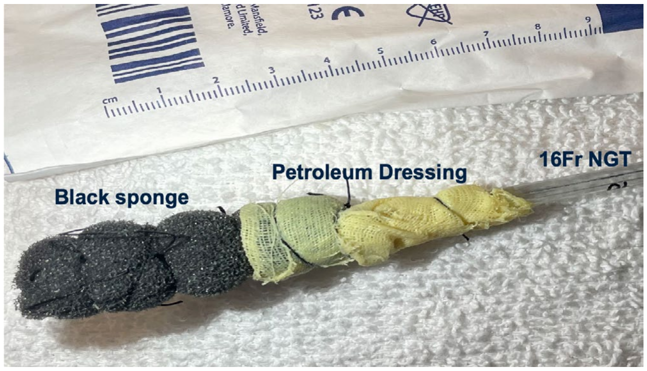

FIGURE 12.10 Black sponge sutured to a 16-French nasogastric tube with petroleum gauze covering part of the sponge to create an endoluminal vacuum-assisted closure.

negative pressure can shrink the defect and facilitate cavity collapse and mucosal apposition. With microdeformation, the cell signaling cascade from the deformation of the local cytoskeleton promotes growth factor release and, thus, cell proliferation. Furthermore, vacuum therapy can increase microvascular density to promote local perfusion and, thus, healing. Finally, vacuum therapy offers exudate control and, thus, helps control the deleterious effects of inflammation that would otherwise prolong wound closure.[76]

EVAC therapy has been demonstrated to be effective in multiple different types of GI tract defects. Prior studies have shown between 67% and 100% effectiveness in esophageal perforation closure without major surgery; however, there can be up to a 9% long-term risk of stricture (though strictures can be managed with dilation). For bariatric leaks, VAC therapy has up to 80% to 90% effectiveness compared with 36% effectiveness in closing a leak with stenting alone.[76] Although published series have been relatively small, EVAC therapy can be an effective adjunct to traditional drainage, stenting, surgical, and other endoscopic techniques for the management of GI tract defects.

ENDOSCOPIC CLOSURE DEVICES

Endoscopic closure techniques have advanced with the development of new technologies to facilitate the approximation of GI tissue. Traditional TTS clips that are used for controlling bleeding can also be used to assist in managing mucosal defects. Enhancements to TTS clips such as endoscopist-controlled rotation, wider clip opening, and prongs to facilitate anchoring on tissue have expanded the utility and effectiveness of TTS clips in managing mucosal defects up to 3 cm. TTS clips are best used for fresh mucosal defects such as those created intentionally either as part of a procedure (e.g., POEM) or inadvertently during a procedure. Because these clips close only the mucosa, they are less effective in the closure of inflamed tissue, such as a perforation not detected during an index procedure or a fistula.

OTS clips are loaded over the tip of an endoscope using specialized caps. An endoscopic tool is then used through the working channel of the endoscope to grab tissue on either side of the defect and pull the tissue within the cap to allow for placement of the cap over the tissue. This allows for the clip to close full-thickness defects up to 2 to 3 cm and incorporate the submucosa into the closure. The success rate in defect closure varies depending on the indication, with the highest success rates seen for closure of intentional defects created during endoscopic resections (92.8%) or in perforations (85.3%). Management of more chronic conditions, such as anastomotic leaks and fistulae, have a lower success rate at 72.6% and 55.8%, respectively. These clips can also be used to manage bleeding from large or refractory ulcers with efficacy in controlling hemorrhage of 86%.[77] Complications of using OTS clips include bleeding, misfiring of the clips with unsuccessful closure or injury to surrounding mucosa (including perforation), clip dislodgment, and migration. Removal of OTS clips is more difficult than removing TTS clips as it requires either a specialized device to cut the clip or the use of bipolar forceps to break a section of the clip.

Endoscopic suturing devices enable the endoscopist to approximate tissue for large defects, such as those after ESD or endoscopic full-thickness resections as well as for perforations and leaks. Two commercially available endoscopic suturing devices are available in North America, both by Apollo Endosurgery (Boston Scientific, Boston, MA), the OverStitch (Boston Scientific, Boston, MA) and the X-Tack (Boston Scientific, Boston, MA). The OverStitch device was originally designed for use with a two-channel therapeutic endoscope, with one channel used to pass a suture and the other to pass a “tissue helix” that screws into and grabs tissue. A single-channel version of the OverStitch is now also available. These devices allow for full-thickness bites of tissue to facilitate the closure of defects or plication of tissue. Published reports of success rates have reported clinical success rates as high as 87.5% in closure of iatrogenic perforations, 83% for intentional mucosal or submucosal defects, and 72% for stent fixation.[78] The X-Tack device is utilized through a standard single-channel endoscope. Helical tacks are screwed into the submucosa or muscle of the GI tract with a suture that passes through the tacks. Once the tacks are placed in the desired configuration around the defect, the suture is tightened and cinched to approximate tissue. As with OTS clips, complications include bleeding, perforation, and suture or tack dislodgement. With the OverStitch device, there is a risk of injuring structures outside of the GI tract because the helix device used to grab full-thickness tissue can puncture structures such as viscera or blood vessels outside the target layer.

These endoscopic closure devices can be used in combination with each other or with other techniques (such as RFA for ablating mucosa or epithelialized fistula tracts during closure procedures). As with the previously described EVAC, endoscopic closure devices are more effective in managing acute to subacute GI tract defects, with effectiveness dropping significantly for chronic defects such as fistulas older than 90 days.

BARIATRIC ENDOSCOPY

With the growth in endoscopic procedures and technologies such as endoscopic suturing devices, there has been a concomitant growth in interest in endoscopic approaches to the management of obesity. Various endoscopic approaches such as endoscopic space-occupying balloons, plication, duodenal mucosal resurfacing, and incisionless anastomotic devices and techniques have been proposed and trialed in the literature; however, only a few of these have obtained regulatory approval from the United States Food and Drug Administration (FDA). Of these, only intragastric space-occupying balloons and endoscopic plication have FDA approval as of 2023.

Intragastric balloons are currently approved in the United States for adults with a body mass index (BMI) of 30 to 35 kg/m^2, whereas in Europe, approval for adults begins at a BMI of 27 kg/m^2.[79] Balloon design varies by manufacturer, but the concept is largely the same. An inflatable balloon is either swallowed or endoscopically placed in the stomach and serves as a space-occupying device to decrease hunger and promote weight loss. Balloons are filled with gas or saline and maintained for 6 to 12 months before they must be removed or replaced. Total body weight loss (TBWL) ranges from 6% to 9.5% in patients with intragastric balloons compared with control patients with TBWLs of 2.8% to 3.4%.[80,81] Complications and adverse effects include abdominal pain, bloating, nausea and vomiting, bacterial overgrowth, and pancreatitis. Death has also been reported as a complication of these devices.[79]

Endoscopic suturing devices have enabled the development of endoscopic sleeve gastroplasty (ESG) or endoscopic plication of the gastric body. Using the OverStitch device, serial sutures are placed from the incisura angularis to the gastric cardia to reduce the size of the stomach, effectively excluding the greater curve of the stomach. The MERIT trial reported that when used in combination with lifestyle modifications, ESG results in a mean TBWL of 13.6% versus 0.8% for a control group of patients with lifestyle modifications alone. Furthermore, 80% of ESG patients in the MERIT trial demonstrated improvement in one or more metabolic comorbidities. At 2 years, 68% of patients in the ESG group maintained a 25% excess weight loss (EWL). The complication rate of ESG was 2% in the trial and included an intraabdominal abscess, bleeding, and malnutrition requiring ESG reversal.[82]

Endoscopic suturing can also be used to manage weight regain after traditional bariatric surgery such as Roux-en-Y gastric bypass. The safety of techniques such as endoscopic transoral outlet reduction (TOR) has been demonstrated in the literature and suggests that patients maintain 25% EWL after TOR at 1 year.[83] In TOR, the gastrojejunal anastomosis is cinched to a smaller diameter by placing an endoscopic purse-string suture around the anastomosis. RFA ablation of the gastric mucosa is typically used in conjunction with suturing to facilitate apposition of the mucosa after plication. While the technique is safe and effective, additional research is necessary to define further which patients would benefit most from such procedures.

With the increased popularity of medical weight loss drugs such as semaglutide, it remains to be seen how endoscopic bariatric procedures may be incorporated into a portfolio of comprehensive management of metabolic diseases.

SUMMARY

Endoscopy is a core competency for surgeons. Knowledge and skills in endoscopic management of GI diseases provide surgeons with essential options to diagnose, treat, and manage not just primary GI diseases but also complications and side effects of surgery. Although not every surgeon should be expected to perform the breadth of diagnostic and interventional endoscopy, surgeons should be aware of endoscopic options to manage GI and surgical conditions to optimize treatment for their patients.

Interprofessional Consultation
Health Equity
Lacking and Future Codes
Future of Telehealth in Surgery

INTRODUCTION

Telehealth is defined by the US Health and Human Services as the ability for a healthcare provider to care for a patient without an in-office visit and includes live conversation by phone or video chat, sent and received messages, or remote monitoring.[1] Benefits and limitations of telehealth—particularly in surgery—are active areas of ongoing investigation. Established benefits include limited exposure to other people with potentially communicable diseases (notably COVID-19) and the elimination of the requirement for patient travel and associated needs (such as time off for work or securing childcare). Other potential benefits include reduced wait time for an appointment and increased access to specialists located in other geographic regions. Limitations include dependence on technology, connectivity, and patient-centered design as well as potential impacts on reimbursement and efficiency.

This chapter will explore current evidence on use of telehealth across the five phases of surgical care as outlined by the American College of Surgeons,[2] the role of policy in supporting and hindering telehealth expansion, and future goals.

Preoperative Phase of Care

The preoperative phase of care encompasses the time from initial decision-making—in which appropriateness of surgical care is determined—until the immediate preoperative phase begins and includes the activities outlined in Table 13.1.[3]

Use of telehealth in preoperative surgical assessment has been evaluated across a variety of procedures,[4–6] and in the published literature it has not been associated with delays to surgery (and in some cases was associated with a shorter time to surgery) or increased complications. Telehealth lends itself well to both reviewing medications and evaluating objective preoperative information—most of these data points are available only via the electronic medical record and can be seen simultaneously by both the patient and the surgical team. Telehealth has also been described for preoperative optimization of chronic disease management[7] and preoperative medical evaluation.[8] Perioperative surgical homes have also been suggested as a way to increase the focus on patient-centered care and have included use of telehealth.[9]

In an assessment of the effect of telehealth visits on financial reimbursement, there was not a difference in the charge-to-collection ratio for telehealth encounters. Although there was a higher ratio of lower-level visits, potential decreases in overall reimbursement may be offset by reallocation of clinic resources or improved patient experience.[10]

In addition to being used for elective preoperative surgical evaluation, telehealth has also been used in the remote evaluation of patients with urgent surgical conditions, including burns and trauma.[11,12] In the burn literature, the majority of patients after telehealth consultation were able to be seen in outpatient clinics for ongoing care.[12] Similarly, in the trauma population, the primary end goals of "teletrauma" have been described as reducing potentially avoidable interfacility transfers and eliminating potentially preventable pretransfer deaths.[12] Although telehealth is less well described in emergency general surgery (EGS), use of virtual triage for patients in free-standing emergency departments (EDs)[13,14] and patients undergoing interhospital transfer to a lower-acuity hospital[15] has been described to be safe and efficient. Recently, the possibility of introducing telehealth consultations to support management decision-making was suggested[16] as a potential intervention to mitigate adverse outcomes known to be associated with the complexity of EGS patients.

TABLE 13.1 **Utilization of Telehealth in the Preoperative Phase of Care**

PREOPERATIVE PHASE OF CARE WORK	ABILITY TO USE TELEHEALTH?
Optimizing chronic disease management	Variable[a]
Coordinating input from multiple disciplines	Variable[a]
Reevaluating the appropriateness of all prescribed drugs	Yes
Evaluating objective preoperative information (labs and other studies)	Yes
Patient education	Yes
Planning for postoperative needs	Unknown

[a] Variable—depends on local resources beyond the surgeon's office.

In the past couple of decades, there has been an increased focus on optimization of the patient in the preoperative phase of care, including enhanced recovery programs (ERPs) and prehabilitation.[17] For ERPs, much of the focus in the preoperative phase is on patient education. The format and delivery of such patient education can vary substantially, and some options can be time and resource consuming. Patient education platforms, created by both electronic medical record vendors and other medical companies, have attempted to leverage the ability of digital communication to provide real-time reminders, virtual checklists, and patient education spaced out across time. Many of the patient education platforms span across the five phases of care, limiting the ability to evaluate the literature assessing the impact specifically in the preoperative space.

It is worth noting that across both preoperative and postdischarge phases of care, the environmental impacts of telehealth may be substantial, though limited data are currently available.[18]

Immediate Preoperative Phase of Care

The immediate preoperative phase of care encompasses the 24 to 48 hours before the time the patient enters the operating room.[3] The work in this phase of care includes dietary instructions (NPO), initiation of surgical bundles, confirmation of procedure (updated history and physical and site marking), and preoperative medication assessment and ordering (e.g., antibiotics, venous thromboembolism prophylaxis, β-blockers). This work is generally best suited to an in-person approach given the need for physical interventions (site marking) and for all parties to be physically present.

In this setting, the greatest benefit of virtual technology may be in communication with the patient's family members or other caregivers to provide real-time updates. Notably, this is somewhat outside the scope of the definition of telehealth because in this case the communication is not directly with the patient. However, it is important to note that this use of technology in the healthcare setting may provide great comfort to families both in providing education about what is happening in the preoperative phase and how their loved ones are progressing through those steps.

Intraoperative Phase of Care

This phase is defined from the time the patient enters the operating room until the time they leave it.[3] The intraoperative phase of care is inherently the most "hands-on"—generally requiring physical presence of multiple team members. Despite this, at least three areas of telehealth use have been explored: remote surgery using robotic technology, remote proctoring of technical skills, and remote consultation for intraoperative decision-making (Table 13.2).

Direct surgical intervention using robotic technology (telerobotics) was first reported on animal subjects in 2002.[19] At least three studies have been published describing telerobotics in human patients.[20] With the primary surgeon operating remotely, a surgeon is still required to be present at the patient's bedside concurrently for port placement, robot positioning, and any unanticipated events or surgical emergencies. Although telerobotic technology has been demonstrated to be feasible, it has lacked widespread uptake to date. In addition to the need for a surgeon at bedside and necessary technology, concerns about latency rates and potential for lost audio or visual connections may be an ongoing barrier. However, it remains a potential opportunity for disseminating surgical expertise to patients who may benefit from advanced surgical skills for whom travel is either not possible or not feasible.

More conceptually appealing and immediately feasible is use of platforms for telementoring— allowing an experienced surgeon to be coached by an expert during acquisition of new skills.[20] Although many robotic systems are set up to facilitate this by default, many independent platforms also exist to provide telementoring regardless of surgical approach.[20–22] Future studies to evaluate the effect of such telementoring in the adoption of new surgical techniques and subsequently surgical care could support the need for infrastructure to facilitate this use of telehealth.

Another use of telehealth in the intraoperative phase of care is remote consultation (teleconsultation). This concept is most commonly applied to consultation with other specialists or primary care physicians, but it may also be considered for intraoperative consultation with surgical specialists or senior surgeons in the setting of unanticipated findings.[16] Though unable to find published descriptions of such processes, in our clinical experience, phone calls are frequently used for this purpose. By definition, telehealth does include phone calls,[1] but it remains unknown if there may be additional benefit to using the technology for telementoring to further the concept of intraoperative teleconsultation. This may also be described as "on-demand telementoring" in which as part of an intraoperative video consultation, the surgeon receiving the consult can participate through shared visualization or even review of surgical video leading up to the time of consultation.

Postoperative Phase of Care

The postoperative phase of care encompasses the time from when the patient leaves the operating room until discharge from the hospital or ambulatory care[3] (Table 13.3).

Virtual critical care may be the most well-known use of telehealth in the postoperative phase of care. A recent scoping review proposed a framework for classifying "use cases" for virtual critical care services (Tables 13.4 and 13.5).[23] The authors concluded that there was proven benefit of a virtual intensive care unit (ICU) for extending coverage and improving compliance but that there had not been demonstrable benefits in terms of reducing transfers.

TABLE 13.2 Utilization of Telehealth in the Intraoperative Phase of Care

INTRAOPERATIVE PHASE OF CARE WORK	ABILITY TO USE TELEHEALTH?
Surgical preincision timeout	No
Operation	Yes
• Surgical techniques	Yes
• Surgical decision-making	
Anesthesia techniques and comorbidity management	No
Antibiotic management	No
Temperature issues	No
Surgical counts and debriefing	No

TABLE 13.3 Utilization of Telehealth in the Postoperative Phase of Care

POSTOPERATIVE PHASE OF CARE WORK	ABILITY TO USE TELEHEALTH?
Anesthesia emergence	No
Recovery room care	Variable[a]
Ongoing treatment and evaluation	
• In the ICU	Yes
• On the hospital units	Yes

[a] Virtual ICU care has been provided in the recovery room.
ICU, Intensive care unit.

TABLE 13.4 Utilization of Telehealth in Virtual Critical Care Services

USE CASE	RATIONALE	PERCENTAGE OF STUDIES	DEMONSTRATED BENEFITS?	FUTURE STUDY OPPORTUNITIES
Extending coverage	Address intensivist shortage, need for additional intensivist coverage, extension of intensivist resources	52%	Yes	Transparent cost analysis
Improving compliance	Adherence to compliance with care bundles, clinical practice guidelines, or care quality initiatives	40%	Yes	Different ICU models
Facilitating transfer	Screening or monitoring of patients before transfer to or from an ICU	8%	No	Other modalities for achieving goals

ICU, Intensive care unit.

TABLE 13.5 Utilization of Telehealth in the Postdischarge Phase of Care

POSTDISCHARGE PHASE OF CARE WORK	ABILITY TO USE TELEHEALTH?
Multidisciplinary coordination of care	Yes
Postoperative assessments	Yes
Rehabilitation	Yes
Medication/treatment adherence	Yes
Collection of patient-reported outcomes	Yes

Though this review demonstrated benefit based in the use case of extending coverage, limited cost analysis makes a clear return on investment difficult to quantify. This would likely depend on the currently available infrastructure at any given location; thus, it may vary significantly for any individual facility.

In a novel approach to the issue of ICU bed shortages, one group used virtual ICU (VICU) services to support patients in the postanesthesia care unit (PACU) before achieving stability for floor care or an ICU bed becoming available.[24] Using this strategic model, almost three-quarters of patients were able to achieve stability for the floor, with an average of 13 hours of VICU care.

As part of efforts to support patient- and family-centered care during the limitations of the COVID-19 crisis, virtual technology was also used to support family interaction with ICU patients. These programs were well received by family members as a service that improved their communication with bedside caregivers and also provided an opportunity to interact with patients when visiting in person was not feasible. Family members noted that these programs could be improved upon with on-demand scheduling, more interactions with care team members, and improved technical aspects such as sound and video quality.[25]

The use of telehealth in the ongoing treatment and evaluation of patients on regular hospital units has included at least three novel areas: virtual sitters for patients, the hybrid Care Hotel model, and Hospital at Home. On the postoperative floor, physical presence is required for the majority of patient care. One notable exception is the use of sitters to monitor patients who are at risk to themselves or others. Video monitoring of patients has demonstrated a reduction in patient falls in several studies, and all studies report cost savings compared with in-person one-on-one monitoring.[26] The studies are limited by small sample size, and better understanding of the benefits and ability to scale will be informative.

At least two models have been described for providing "inpatient care" outside of the walls of the hospital—the hybrid Care Hotel and Hospital at Home. Both use components of telehealth to assess and provide care for patients. The Care Hotel was developed at the Mayo Clinic in Florida and combined daytime in-person registered nurse (RN) monitoring of postoperative patients and 24-hour virtual RN telemonitoring in a hotel setting. Patients are provided technology for vital sign monitoring as well as a tablet with video visit capability through which they can also connect with physicians and advanced practice providers. Patients were selected based on having undergone a low-risk procedure and an active choice to participate in the program after learning about it. Overall, patients reported a positive experience and were likely to recommend it to others.[27]

Moving even further away from the walls of the hospital, the Hospital at Home concept has been used similar to the Care Hotel to provide an inpatient level of care in a location more comfortable for patients for over a decade. Similarly, this concept typically combines some version of in-person care (such as daily paramedic visits) with virtual physician rounding, vital sign monitoring, and a 24-hour escalation/help line. The benefits of Hospital at Home have been demonstrated in multiple studies and meta-analyses, but they had not been effectively scaled because of barriers to reimbursement and lack of standards regarding equity, quality, and safety.[28] The COVID-19 pandemic provided impetus for implementation and rapid scaling of such virtual strategies across many settings.[29] However, Hospital at Home has been primarily implemented in patients with medical diagnoses, with increasing interest in exploring its benefit for surgical patients.[30] A recent pilot study of 24 patients demonstrated feasibility for preoperative and postoperative patients.[31]

Although telehealth is most commonly conceptualized as supporting patients before and after hospitalization, the previous examples provide strong evidence that with creative problem-solving, many uses may be beneficial even in the postoperative phase of care.

Postdischarge Phase of Care

The postdischarge phase of care begins when the patients are discharged from the care facility (hospital or surgery center) and ends when they have completely recovered from their surgical care.[3]

Possibly the most studied phase of care with regard to surgical telehealth is the postdischarge phase. Numerous observational studies and a randomized controlled trial have shown equivalent safety of substituting telehealth visits for in-person visits for routine postdischarge visits, particularly in lower-risk, elective procedures.[32–34] Advantages to the patient for these virtual visits include less time off from work and distance traveled, with high rates of patient satisfaction with no increase in hospital resource use with regard to ED visits, observation, or inpatient admissions.[35] Although this was an active area of research investigation in the years before the COVID-19 pandemic, a comparison of the impact of the rapid expansion to a less stringent patient population in the setting of the pandemic demonstrated no increase in healthcare use.[36]

Another area of investigation is whether app-based postdischarge patient engagement applications (a subset of mobile health [mHealth] applications) can be used for patient monitoring to detect complications earlier and reduce the need for hospital resource use.[37] This may include remote monitoring of medication adherence, physiologic parameters, and images of wound healing. Identification of patients whose postoperative healing is not following the expected trajectory may prompt surgical or other teams to schedule an urgent outpatient visit and coordinate outpatient management resources when available. Extensive heterogeneity exists in these applications because they have been developed by vendors of electronic health records, stand-alone startups, and individual institutions. Well-controlled studies examining the effectiveness of patient engagement applications for improving patient engagement, activation, outcomes, and satisfaction are nascent.[38] Several observational studies suggest that mHealth applications can decrease hospital resource use such as length of stay and readmission. These applications also create an opportunity to collect patient reporting outcomes at multiple time points in the recovery process.[39,40] When paired with wearables and smart devices, patient physiologic data can also be collected in greater quantities and at more time points than would be otherwise feasible.

Beyond the routine postdischarge clinic visit and active patient monitoring, telehealth applications can also be useful for providing "as-needed" education and a platform for communicating with the surgical team with questions or concerns that arise. Traditionally, patient education is provided in multiple ways—typically including a verbal review with the surgical team, verbal review with the discharging nurse, and written instructions in a discharge document (often referred to as an *after visit summary*). At these times, the postoperative course of the patient remains largely unknown, and so efforts are made to cover a wide range of common topics that may or may not arise for that particular patient. Mobile applications offer the option to have this educational information available in an electronic format that is available to patients in a variety of methods—they can be assigned to review on particular days or be found by the patient using a search tool for their current symptoms. For example, narcotic-related constipation can be one cause for postoperative pain and even visits to an ED. If patients are asked specific questions about their recent bowel movements, education about constipation can be presented or not, depending on the patient responses. This may offer the opportunity to streamline the education for the patient and deliver information in an as-needed, digestible format. Though educational resources can be quite effective at answering the most common questions, there is always the possibility of the patient having concerns that are not fully addressed. Using secure messaging on an electronic platform likely allows for more efficient review and triage than traditional phone calls, which require both parties to be available for a conversation at the same time.

It is important, as noted in the prehospital phase, to acknowledge that many applications are designed to encompass the entire surgical episode of care across one or more phases. The design of a telehealth complement to each traditional surgical phase must be tailored to individual institutional practices and should involve multiple stakeholders, including patients and caregivers. In a recent qualitative study examining patient and caregiver feedback in the design of an mHealth tool for total hip replacement, participants noted that push messaging should be used only to convey urgent information and solicit immediately necessary information.[41] Less urgent communication could be sent via an application accessible on demand or via email. Patients also noted that actionable information should be included in the body of the text rather than referring the patient to another resource. Lastly, as hospital processes and patient care pathways evolve, there should be a systematic way of ensuring that mHealth applications are updated in a regular, timely fashion.

One additional challenge of telehealth across all phases of care is the potential for technology barriers and challenges for patients. In a qualitative analysis of patient experience comparing in-person to virtual postdischarge visits after low-risk surgeries, patients were noted to value quality of care, efficiency, and convenience in both settings, with the barriers being different for the two options.[42] As discussed further later, usability and impact on disparities are areas for future research.

HEALTH POLICY, REIMBURSEMENT, AND HEALTH EQUITY

Reimbursement for telehealth continues to evolve as the COVID-19 pandemic comes to a close. Policies that were rapidly expanded on a temporary basis must now be codified permanently or be phased out. As of spring 2023, all 50 states retain Medicaid coverage for synchronic live video visits, 36 cover audio-only visits, 34 states cover remote patient monitoring, and 28 states cover asynchronous store-and-forward visits. There remains a jumble of rules regarding eligibility with regard to originating site (home, work, school, clinic, hospital) and provider types (with expansion to physical therapy and speech pathology services in some states). With regard to private payers, 24 states now mandate telehealth reimbursement parity, meaning that telehealth visits must be reimbursed at the same level-for-level service as an in-person visit. The number of states with this requirement has been stable in the past year. Ongoing updates to state-by-state telemedicine reimbursement coverage can be found at the Center for Connected Health (www.cchpca.org).

This section will focus on Centers for Medicare and Medicaid Services (CMS) guidelines for telehealth. Telehealth reimbursement requirements for specific commercial payers may have additional requirements. This section starts with a short review of evaluation and management Current Procedural Terminology (CPT) codes that are likely familiar to many surgeons. A more substantial portion of the review will be dedicated to newer and evolving codes in remote physiologic monitoring, remote therapeutic monitoring, and interprofessional consultation and how they may be applicable to surgical practices.

Synchronous/Real-Time Audio-Video Visits Requiring Face-to-Face Interaction With Patients

99202 – 99205	Telehealth visits for the evaluation and management (E&M) of a new patient.
99211 – 99215	Telehealth visits for the evaluation and management of an established patient.

These sets of codes require "place of service" modifiers, which vary by payer.

Audio-Only Telephone Communications

99441 – 99443	Evaluation and management services provided to an established patient unrelated to an E&M service provided within the last 7 days and will not lead to an E&M service within the next 24 hours.

E-Visits Not Requiring Face-to-Face Interaction With Patients (e.g., App-Based Messages or Portal-Based Messages)

99421 – 99423	For established patients. These codes are billed by cumulative time over 7-day periods.

Virtual Check-Ins

G2010	Review and recommendations originating from recorded video or images (store and forward) submitted by a patient, unrelated to an E&M service provided in the past 7 days. Physicians must review and respond within 24 hours. If the images or video are concerning enough to warrant an E&M visit within 24 hours or soonest available visit, then this code cannot be billed.
G2012	Brief communication originating from a patient. Physicians can respond by telephone, audio/video, secure text messaging, email, or patient portal.

REMOTE PHYSIOLOGIC MONITORING

There is currently no stand-alone CMS reimbursement for specific patient education or patient engagement applications—though depending on pathway configuration within the digital engagement applications, some preexisting codes for remote patient monitoring may apply if a monitoring device is paired with the engagement application. Current codes exist for remote monitoring of physiologic data such as weight, blood pressure, pulse oximetry, and/or respiratory flow rate using a digitally connected device. These codes may be relevant to patients participating in a digitally enhanced prehabilitation program before surgery.[43] For example, surgeons or their designated nonphysician providers may place a patient on a supervised walking and weight loss program before surgery and use a digital scale to transmit daily weights for monitoring, allowing providers to advise on patient progress over the course of a month, in which case 99091 would be applicable. If review and advice is delegated to a nurse (or a medical assistant in some states), 99457 would be applicable. Another example could be a thoracic surgeon placing a patient on a prehabilitation program in anticipation of anatomic lung resection for lung cancer. The patient is given a remote digitally enabled spirometer and instructed on its use. The surgeon or delegated nonphysician provider would be able to provide monitoring and advice on the prehabilitation program using the spirometer data.

Remote Physiologic Monitoring Codes

99091	Collection and interpretation of physiologic data (e.g., ECG, blood pressure, glucose monitoring) digitally stored and/or transmitted by the patient and/or caregiver to the physician or other qualified healthcare professional, qualified by education, training, and licensure/regulation (when applicable), requiring a minimum of 30 minutes of time, each 30 days.
99453	Remote monitoring of physiologic parameter(s) (e.g., weight, blood pressure, pulse oximetry, respiratory flow rate), initial; setup and patient education on use of equipment. (Initial setup and patient education of monitoring equipment.)
99454	Device(s) supply with daily recording(s) or programmed alert(s) transmission, each 30 days. (Initial collection, transmission, and report/summary services to the clinician managing the patient.)
99457	Remote physiologic monitoring treatment management services, 20 minutes or more of clinical staff/physician/other qualified healthcare professional time in a calendar month requiring interactive communication with the patient/caregiver during the month. (Interpretation of the received data and interaction with patient on a treatment plan by a clinician.)
99458	Remote physiologic monitoring treatment management services, additional 20 minutes or more of clinical staff/physician/other qualified healthcare professional time in a calendar month requiring interactive communication with the patient/caregiver during the month.

REMOTE THERAPEUTIC MONITORING

Remote therapeutic monitoring codes have been approved for respiratory and musculoskeletal conditions with the intention to expand the code list to encompass other body systems. These codes differ from the remote physiologic monitoring codes in that a physiologic monitoring device (blood pressure cuff, heart rate monitor, digital thermometer, digital scale, pulse oximeter, glucometer, spirometer) can also be used but is not required. Examples of remote therapeutic monitoring include monitoring medication adherence, pain levels during at-home physical therapy, and the need for rescue medications for people with asthma in which the patient enters self-reported data into a device or application designated as a medical device.[43] Again, relevant applications of these codes in the surgical setting would include prehabilitation in preparation for surgery. For example, before surgery, the surgeon places the patient on a smoking cessation program, and the patient self-reports their progress in an appropriate application.

Remote Therapeutic Monitoring Codes

98975	Remote therapeutic monitoring (e.g., respiratory system status, musculoskeletal system status, therapy adherence, therapy response); initial setup and patient education on use of equipment
98976	Remote therapeutic monitoring (e.g., respiratory system status, musculoskeletal system status, therapy adherence, therapy response); device(s) supply with scheduled (e.g., daily) recording(s) and/or programmed alert(s) transmission to monitor respiratory system, each 30 days
98977	Remote therapeutic monitoring (e.g., respiratory system status, musculoskeletal system status, therapy adherence, therapy response); device(s) supply with scheduled (e.g., daily) recording(s) and/or programmed alert(s) transmission to monitor musculoskeletal system, each 30 days
98980	Remote therapeutic monitoring treatment management services, physician/other qualified healthcare professional time in a calendar month requiring at least one interactive communication with the patient/caregiver during the calendar month; first 20 minutes
98981	Remote therapeutic monitoring treatment management services, physician/other qualified healthcare professional time in a calendar month requiring at least one interactive communication with the patient/caregiver during the calendar month; each additional 20 minutes (list separately in addition to code for primary procedure)

INTERPROFESSIONAL CONSULTATION

These codes are applicable when a consultant's services are required when the consultant does not directly interact with the patient. The consultant performs telephone, Internet, or electronic health records review (e.g., imaging, laboratory values, pathology results) and communicates advice on management back to the treating physician, who has had a face-to-face interaction with the patient. If the advice is adequate so that it does not lead to a consult visit between the consulting physician and the patient, these codes can be used.

An application of this code in surgical practice could be determining the need for transfer and surgical consultation. For example, an emergency room physician from a free-standing emergency room could consult a surgeon taking call at a hospital on the necessity of transferring a patient for further workup for abdominal pain. The consulting surgeon could review the patient's electronic medical record for vital signs, imaging, and laboratory values and discuss the patient's physical examination with the requesting physician. If a transfer is not warranted, both the requesting physician and the consulting surgeon could use interprofessional consultation codes. Another application of these codes may be the virtual review of a wound to determine whether local wound care is sufficient or transfer for surgical debridement is necessary. The specific code most appropriate to the situation depends on the time spent in review of information and the mode and time spent communicating recommendations back to the requesting physician.[44]

Interprofessional Consultation Codes

99446	Interprofessional telephone/Internet/electronic health assessment and management service provided by a consultative physician or other qualified healthcare professional, including a verbal and written report to the patient's treating/requesting physician or other qualified healthcare professional; 5–10 minutes of medical consultative discussion and review
99447	11–20 minutes of medical consultative discussion and review
99448	21–30 minutes of medical consultative discussion and review
99449	31 minutes or more of medical consultative discussion and review
99451	Interprofessional telephone/Internet/electronic health assessment and management service provided by a consultative physician or other qualified healthcare professional, including a written report to the patient's treating/requesting physician or other qualified healthcare professional, 5 minutes of medical consultative discussion and review
99452	Interprofessional telephone/Internet/electronic health record referral service(s) provided by a **treating/requesting** physician or other qualified healthcare professional, 30 minutes

HEALTH EQUITY

Although telemedicine in surgery has the potential to improve issues of health equity, particularly in terms of access to specialty care, the implementation of such technologies must be carefully structured to avoid exacerbating disparities. Early data suggest that implementation of telemedicine without addressing technologic or language barriers may further disadvantage certain populations. Twenty-one million Americans lack access to reliable broadband Internet access at home. While state and local governments address this infrastructure issue, telehealth providers and vendors can seek to develop low-bandwidth solutions. Medicare has had consistent coverage of telehealth services; however, state-based Medicaid providers and commercial payers have had varying and inconsistent coverage of these services. Lastly, current patient engagement applications are typically designed only in English, leading to underutilization among non–English speakers.[45–48]

LACKING AND FUTURE CODES

There are currently no CMS codes that could be applicable to planned or on-demand telementoring or teleproctoring. Surgeons who are adopting new technologies or new techniques while in practice would likely benefit from telementoring and teleproctoring. Current proctoring models typically require either the expert surgeon or the learning surgeon to travel to a different hospital. When encountering unusual pathology or unusual anatomy, digitized operating rooms now have the capability of allowing a senior or expert surgeon to call into the operating room and view in real time what the operating surgeon is seeing. However, there are no current reimbursement frameworks for these intraoperative consultations. As these technologies permeate operating rooms and enable more complex procedures to be performed closer to where patients live, reimbursement frameworks will need to evolve.

FUTURE OF TELEHEALTH IN SURGERY

There has been an explosion of technologies, tools, and new companies in the telehealth space, many of which target the surgical realm. As these technologies are piloted, integrated, and tested, robust studies are needed to prove their value to patients, surgeons, hospital systems, and payers. Further work also needs to be done in order to ensure that these new technologies bridge rather than exacerbate preexisting health equity issues. The future of telehealth in surgery is bright. If implemented correctly, telehealth has the potential to expand access to surgical specialists, improve prehabilitation, provide platforms for earlier detection of complications, enhance surgical decision-making in the operating room, and reduce healthcare costs.

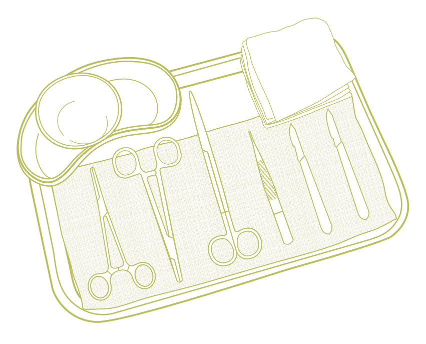
14 CHAPTER



Health Inequities and Disparities in Surgery

Tanya L. Zakrison, Anthony Douglas, Mihir Chaudhary, Marc de Moya, and Cherisse Berry

OUTLINE

Introduction
Historical Context and Evolution
- Indigenous and African American Populations
- Race as a Social Construct
- Preventable Mortality of Indigenous and African American Populations
- Historical Overview of Surgical Disparities
- Racial Capitalism and the US Healthcare System
- Physiologic Impact of Racism and Discrimination

Dimensions and Demographics of Disparities
- Females
- Lesbian, Gay, Bisexual, Transgender, Queer, Plus (LGBTQ+) Patients
- Surgical Disparities and Geographic Factors
- Impact of Poverty and Economic Inequality on Surgical Disparities
- Surgical Disparities in Immigrant and Refugee Populations
- Mass Incarceration and Surgical Disparities
- Intersectionality and Surgical Disparities

Underlying Causes of Disparities in Surgery
- Individual and Provider Factors
- Institutional Factors
- Systemic Factors

Tackling Surgical Disparities: A Strategic Framework
- Identifying Disparities
- Reducing and Mitigating Disparities
- Eliminating Surgical Disparities
- Healing Disparities

Conclusion

INTRODUCTION

Surgical disparities refer to potentially preventable differences in the availability, accessibility, and quality of surgical care that lead to differential surgical outcomes experienced by distinct populations. These disparities manifest as variations in surgical morbidity, mortality, and complication rates, which are often influenced by a patient's race, ethnicity, gender identity and sexual orientation, social class, geographic location, and a host of other demographic and systemic factors. *Inequity* pertains to the unjust or unfair distribution of resources or opportunities, whereas *inequality* highlights distinctions or variations among different groups or individuals, and *disparity* points to quantifiable differences or gaps in access, opportunities, or results.[1]

Such disparities in surgical care present a uniquely complex challenge with deep historical and political roots. Fundamental to understanding these disparities is the concept of surgical access—the cornerstone of surgical equity. It encompasses not only the quality of outcomes after surgery but also the entire spectrum of surgical care, from initial consultation to complete recovery and efforts to prevent surgical disease and injury.

Racial and socioeconomically disadvantaged groups, including rural populations, face limited access to quality healthcare and elevated mortality rates in various surgical procedures—ranging from abdominal aortic aneurysm repair to coronary artery bypass, trauma care, spine surgery, and bariatric surgery.[2] Provider bias, disparities in surgery rates for cancers, and underutilization of advanced surgical techniques contribute to unequal healthcare provision. Differences in hospital volumes and social determinants of health amplify disparities, with Black and Hispanic patients experiencing 42% and 21% higher postoperative mortality risks, respectively, necessitating systemic changes to address these critical public health concerns.[3] These disparities also extend to the pediatric postsurgery population.[4]

Surgical disparities also extend beyond individual patient care and into the domain of public health, with broad implications that include increased morbidity and mortality rates in underserved populations, which contribute to diminished life expectancy and quality of life. These disparities exacerbate economic burdens through heightened healthcare costs and lost productivity, perpetuating a cycle of inequity that undermines community well-being. Addressing surgical disparities is therefore a crucial element of public health that promises to enhance population health, ensure health security, and foster resilient health systems.

With the growing emphasis on enhancing the standardized nature of surgical care, the persistence of such discordant patient

BOX 14.1 Surgical Disparities

Increased Healthcare Costs: Disparities in surgical outcomes result in longer hospital stays and intensive care, ultimately increasing overall healthcare expenses absorbed by the system and society at large.

Resource Allocation: Redirected resources to manage complications from disparities leave fewer funds for preventive care, potentially lowering the overall health of the population.

Economic Productivity: Poor surgical outcomes leading to longer recovery times or disability can reduce patients' economic contributions, affecting overall productivity and economic stability.

Social Inequity and Cohesion: Surgical disparities exacerbate social inequities, eroding trust in the healthcare system and fostering social fragmentation.

Public Health Risks: Substandard surgical care can contribute to infectious disease spread, posing public health risks that require equitable interventions for effective disease control.

Moral and Ethical Implications: A society overlooking surgical disparities may compromise ethical principles, risking international reputation and potential economic consequences.

Opportunity Costs: Addressing consequences of surgical disparities diverts resources from areas like education and innovation, potentially hindering societal development.

experiences poses continued threats to high-quality healthcare. This chapter seeks to dissect the persistent phenomenon of surgical disparities, analyze the multifaceted nature of their occurrence, and outline the concerted efforts required to ensure equitable surgical care for all. By dissecting the pathways that lead to these disparities and the multifaceted interventions to address them, surgeons can contribute to a transformative change, one that ushers in a healthcare system in which surgical care is universally accessible and equitable—a fundamental human right that transcends race, geography, and socioeconomic status.

This chapter offers a comprehensive overview of surgical disparities, from their historical underpinnings to modern efforts to identify, reduce, eliminate, and repair their impacts. It provides a blueprint for healthcare professionals, policymakers, and researchers interested in understanding and addressing these vital issues.

How do surgical disparities affect all members of society?

Surgical disparities can have a detrimental impact on society, including those who do not directly experience these disparities; these impacts take several forms (Box 14.1).

Surgical disparities thus have far-reaching implications that extend well beyond the health of the directly affected individuals. The effects are economic, societal, and ethical, challenging the fabric of community health and the effectiveness of the entire healthcare ecosystem.

HISTORICAL CONTEXT AND EVOLUTION

To better understand the root of contemporary healthcare disparities in the United States, it is valuable to delve into the historical context shaping the marginalization of specific groups. Such historical context is inseparable from the surgical disparities experienced by these groups today.

Indigenous and African American Populations

The United States, as a social and political entity, was established on the basis of settler-colonial violence that displaced Indigenous populations to give way to economic exploitation by dominant forces, a persistent legacy seen in various countries worldwide.[5] Historical trauma—such as the Dawes Act of 1887 that altered economic and societal structures within Indigenous communities by parceling nonarable land, causing starvation and the forced domestication of Indigenous females—has resulted in the health disparities seen today.[6,7] These lingering effects and the forced assimilation within boarding schools (the Indian Civilization Act of 1819) continue to affect Indigenous health outcomes, contributing to intergenerational disparities and barriers to effective healthcare access.[8] Structural injustices range from high rates of violence against Indigenous females (historically with no legal mechanism to prosecute White perpetrators) to the chronic underfunding of the Indian Health Service to limited representation in research, causing statistical erasure. These issues underscore the need to understand this historical context to advance equity in surgical care.[9–14]

In the United States, chattel slavery began with the forced arrival of the first African slaves in Jamestown, Virginia, in 1619. From that point onward, slavery became an integral part of the American economy and persisted until the passage of the 13th Amendment to the US Constitution in 1865, which abolished slavery, except in the case of incarcerated human beings.[15] Slavery played a significant role in generating immense wealth for the US economy, starting with the agricultural sector. The forced labor of enslaved individuals contributed to the success of cash crops such as tobacco, rice, sugar, and especially cotton, which became a crucial part of the economy both nationally and globally. Slavery is the root historical institution driving much of modern-day structural racism—residential segregation, exclusion from formal economies, inherited neighborhood poverty—that drives much surgical disparity, from the differential incidence of violent injury among Black Americans to the inability to access appropriate cancer screening, among other disparities. Although the rapid erasure of Indigenous populations for land accumulation was central to the US settler-colonial project, the "one-drop rule" (of African blood) expanded the pool of exploitable human beings governed by state-sanctioned violence, and both were foundational to the structural racism and racial capitalism (a concept that asserts that racialized exploitation and capital accumulation are mutually reinforcing) of today.[16]

Race as a Social Construct

Race is a social construct used historically to justify inequalities and establish power dynamics, rather than reflecting biologic differences.[17] The concept of "racialization" involves categorizing individuals based on physical attributes to perpetuate social, economic, and political hierarchies, leading to systemic discrimination and unequal access to resources.[18] As mentioned, this practice has deep roots in slavery and racial capitalism, shaping present-day disparities and injustices. Understanding race as a societal creation is essential in combating systemic racism and promoting a fairer, more equitable society. To effectively dismantle structural racism that perpetuates health inequities, future public health practitioners need to familiarize themselves with the concept of racial capitalism and employ it as a critical framework to address all public health issues.[19] This is key to eliminating surgical disparities.

Preventable Mortality of Indigenous and African American Populations

The devastating loss of Indigenous peoples and enslaved Africans in the United States and the Americas stemmed from European colonization, forced displacement, and the transatlantic slave trade. Although exact figures are hard to determine because of the limited documentation, these populations suffered significant casualties. These tragic events left lasting impacts on Indigenous and African-descendant communities, contributing to an enduring legacy of oppression and displacement. For instance, more than 56 million Indigenous persons perished over a century as a result of European settlers, representing a staggering 90% of the population, even contributing to a decline in carbon dioxide production in the Americas.[20] Today, the American Indian and Alaska Native populations in the United States stand at 9.7 million (2.9% of the population), and they have the lowest life expectancy compared with other groups, at 73.1 years (vs. 78.9 years for Whites).[21,22]

Over 2 million slaves died during the Atlantic crossings to the United States, with a mortality rate of up to 30%.[23] Enslaved human beings had a life expectancy of 22 years, compared with 40 years for White individuals.[23] Systemic violence and racial terror were pervasive and normalized, for example, with the practice of lynching; nearly 4500 individuals were lynched from 1883 to 1941. Photos of tortured, burned, and lynched human beings were printed on US postcards and remained in circulation until 1908.[24,25] Fleeing racial terror in the South led to the 1915–70 “Great Migration” of internally displaced refugees to segregated cities, leading to health disparities.[26] Today, African Americans face disproportionately high premature death rates, totaling 74,000 preventable deaths annually in the United States.[27] African American males face a 1-in-1000 risk of police killings in the United States, identified as a violation of human rights, with repeated human rights reports from the United Nations on the subject.[28,29] The preventable killings of Michael Brown, Eric Garner, Sandra Bland, Trayvon Martin, George Floyd, Ahmaud Arbery, Breonna Taylor, and many others launched the Black Lives Matter movement and exemplify ongoing injustices and systemic failures, with surgical societies and federal research agencies identifying structural racism as a significant threat to public health.[30–33] In fact, given the privatization of the educational system, the prison-industrial complex, the criminalization of asylum seekers, and other examples, certain billionaires in the United States not only stymie public health approaches to reduce disparities but also continue to profit off the harm it creates.[34]

Historical Overview of Surgical Disparities

The history of surgical disparities is entwined with healthcare inequality, influenced by socioeconomic barriers, racial segregation, and institutional biases. After the abolishment of slavery, laws and policies rooted in structural racism were designed and implemented to maintain White privilege and White supremacy, resulting in significant healthcare disparities and inequities among racial/ethnic minoritized populations. During the Jim Crow and Black codes era, when segregation was legalized by the Supreme Court in *Plessy v. Ferguson*, Black patients faced inferior hospital care, limited health insurance access, and underresourcing of segregated hospitals, and they still received a lower quality of care in underfunded hospitals as a result of segregation.[35] The Jim Crow laws, which legalized racial discrimination in Southern US states from the late 1870s through the mid-1960s, fueled place-based racism by enforcing segregation, creating racially segregated communities with disparities in resources, opportunities, and life expectancy. These policies led to unequal access to education, healthcare, and economic opportunities, perpetuating cycles of poverty and inequality in many neighborhoods, which persist today. This led directly to the segregation currently seen in many cities across the United States, compounding the racial wealth gap by underresourcing public schools funded by property taxes in de facto segregated neighborhoods. Health outcomes for segregated populations were negatively affected by higher mortality rates for Black infants and adults alike under Jim Crow segregation.[36,37] Even breast cancer receptor status has been associated with place-based segregation and Jim Crow laws.[38] The closure of medical schools serving racialized minorities after the Flexner Report worsened access, underlined by the 1985 Secretary’s Task Force on Black and Minority Health.[39–41] Deliberate policies like the Anti-Drug Abuse Act of 1986 further marginalized Black and Brown individuals by causing mass incarceration, disrupting the civil rights and peace movements, hindering educational access to postsecondary education, and worsening disparities in health.[42–46] Landmark reports like the 2002 *Unequal Treatment* and ongoing studies underscore disparities in surgical services and care quality, thus shaping healthcare policies.[47] Even as laws changed across the country to render official segregation illegal, the official mindset of mainstream White society, which tolerated such segregation and ill treatment, has demonstrated little atonement. Racism is a deeply ingrained system of racial advantage and hierarchy that pervades US society, making it almost inescapable. Similar to how citizens in a capitalist society inherently support capitalism regardless of their personal beliefs, individuals in a racist society inadvertently perpetuate racism, regardless of their personal stance on racism.[48]

Health disparities stemming from the entrenched structural racism of the United States have been extensively documented, with three salient domains as described by Bailey et al.[49] elucidating the relation to health outcomes at both individual and population levels:

1. **Historical Redlining and Racial Segregation:** The Home Owners’ Loan Corporation’s discriminatory “redlining” practices, arising during the 1933 Great Depression recovery, exacerbated socioeconomic disparities. It was intended to guide banks and other mortgage lenders in deciding which areas within cities were safest for investment. Neighborhoods were color-coded, with green deemed the least risky for loans, followed by blue and yellow. The neighborhoods colored red were considered “hazardous” or too high risk for obtaining government-backed home loans. This systematic denial of mortgages in Black neighborhoods hindered capital access and limited homeownership for African Americans while fostering predatory lending. This widened the racial wealth gap, as highlighted by the Federal Reserve Bank of Boston’s 2015 report, which showed Black families averaging just $8 in assets compared with White families with around $247,500.[50] These economic discrepancies underscore how power, money, and resources influence health outcomes, with similar disparities affecting Latino families’ median wealth and assets compared with White households. Research suggests that redlining contributes poverty, segregation, lack of healthcare insurance, and higher rates of firearm-related violence, posing challenges in acute care surgery, particularly concerning trauma prevention strategies.[51,52]
2. **Systemic Inequity in Law Enforcement and Incarceration:** The US criminal justice system demonstrates clear racial disparities, evidenced by the highest global incarceration rate and racially differential treatment across various procedural stages—from police encounters to sentencing.[43] As mentioned earlier, African American males face a 1-in-1000 risk of premature mortality at the hands of law enforcement in the United

States.[28] This systemic bias extends to health concerns because individuals in carceral systems, particularly those of African descent, face significant health risks, including inadequate preoperative assessments and surgical care, as well as insufficient postmortem investigations, including after torture.[53–57] Such systemic neglect signifies a broader issue of health service delivery within this population. Even the differential application of the Second Amendment (itself a legacy of White supremacy, granting Virginia's desire to control armed state militias to quell slave uprisings) has led to racial disparities in firearm mortality from Stand-Your-Ground Laws.[58]

3. **Healthcare Inequalities Rooted in Racist Ideologies:** The US healthcare system bears the legacy of scientific racism and eugenics, ideologies that leveraged purported biologic racial differences to justify inhumane treatment and inequality. Historical figures in medicine, such as Samuel Cartwright and J. Marion Sims, exemplify this legacy through their racially biased medical theories and practices—such as nonconsensual surgical experimentation (torture) on enslaved Black females and males—that have shaped current medical practices and beliefs.[59,60] For example, contemporary medical students in the United States believe that Black patients perceive pain less than White patients.[61] This history underscores the need for a critical examination of persistent biases and systemic barriers in medical care for people of color.

Racial Capitalism and the US Healthcare System

Surgeons should grasp the historical context of the American healthcare system—a complex evolution influenced by social, economic, and political factors over centuries. Unlike other high-income nations with universal healthcare, the US system relies on a mix of private and public insurance. The rejection of universal healthcare, tied to racial capitalist structures, historically excluded African Americans, and later other people of color, from insurance and healthcare access. This was based on the false notion of racial inferiority—illustrated in the works like influential statistician and eugenicist Frederick Hoffman's racially biased writings that guided US policy for over 100 years.[62] The health of freed enslaved people was of no concern to the federal government—in fact, just the opposite, as free and healthy former slaves could upend the racial hierarchy. Denied the ability to survive or to access resources or healthcare, the premature mortality then witnessed was attributed to the intrinsic inferiority of Black people.[63,64]

Although the post-Great Depression New Deal, instituted in 1933, transformed various facets of American society and politics, it upheld the racial order. Key achievements were built on discriminatory practices, such as excluding African Americans and Mexican Americans from labor rights via the National Labor Relations Act and harming Native communities through infrastructure projects. Further racist policies of the New Deal included sytemic housing discrimination, the Agricultural Adjustment Act, the Social Security Act, and many more. Additionally, it enacted Executive Order 9066, leading to the internment of approximately 120,000 Japanese Americans during World War II.[65] President Truman's 1945 push to expand the US hospital system reinforced healthcare segregation through the Hill-Burton Act, exacerbating racial disparities in access to quality healthcare, notably in the South. This era saw Black Americans marginalized from medical societies (such as the American Medical Association [AMA]) and educational opportunities, prompting the establishment of independent healthcare systems and organizations within Black communities. Early attempts at universal healthcare were thwarted to prevent African American inclusion, and access to healthcare through employment benefits and union rights was often denied to African Americans as a result of industry disparities in access to employment opportunities. Access to quality medical care was fundamentally contingent on an employer-based insurance system, which inherently presented substantial barriers to Black Americans in securing such benefits. Even when Black individuals were insured, quality hospitals were segregated, caring only for White patients.[63] The National Medical Association (NMA), established by Black physicians in 1895, has sparred with the AMA ideologically for decades over nationalized health plans, reflecting broader debates on healthcare as a fundamental right versus a market commodity. Federal initiatives like Medicare and Medicaid were eventually established to address legal segregation in healthcare but left gaps in access, with Medicaid representing Congress's concession to Southern states unwilling to concede federal funds for the provision of equal healthcare for poor and Black people.[66–68] Despite progress through initiatives like the Affordable Care Act, racial healthcare inequalities persist as a result of resistance to Medicaid expansion, with stark consequences for public health and disparities that transcend racial lines.[69]

The healthcare industry, valued at over $3 trillion, wields significant influence by dictating prices and lobbying against unified government payment systems, boosting its own profits. Key players like insurance companies, pharmaceutical industries, and the AMA spend millions in lobbying activities, shaping government policy and influencing lawmakers.[70] A recent Gallup Poll demonstated that in 2024, 62% of Americans believe the federal government has a responsibility to ensure healthcare coverage for all citizens, reflecting growing public anger and dissatisfaction with the profit-driven insurance system.[71] In 2018, Goldman Sachs questioned whether curing patients was indeed a sound business model.[72] The US healthcare system, marked by higher costs and mortality rates compared with public models, faces significant challenges in achieving quality care comparable to that of other nations, ranking low in global healthcare assessments. Racial inequities in care have, in fact, persisted for six decades and widened in recent years, suggesting the persistence and even fortification of structural racism in healthcare access.[73] Strides toward equitable healthcare must address market-oriented obstacles, advocate for universal access to care, and disengage from profit-driven models prevalent in the US healthcare sector.

The challenges posed by the healthcare industry's influence and structural inequalities require thorough examination and comprehensive systemic changes to achieve fair healthcare access and enhanced health outcomes, especially for racialized and underserved communities.

Physiologic Impact of Racism and Discrimination

The ripple effects of discrimination result in healthcare provider shortages in underserved areas, strained trust between marginalized groups and healthcare providers, biased patient-provider interactions, and a lack of racial diversity in medical professions. Additionally, systemic discrimination can lead to "weathering," in which chronic stress and discrimination affect physical and mental health.[74] This sustained exposure contributes to allostatic load, which heightens the risk of severe health conditions like cardiovascular disease, diabetes, obesity, and mental health disorders, underscoring the long-lasting repercussions of stress on health and surgical outcomes.[75–77] For example, a US study found that differences in rates of hypertension between Black and White respondents were substantially reduced by considering reported experiences of and responses to racial harassment.[78] Allostatic load can, in fact, increase in wealthier racialized minorities who experience more scrutiny from and discrimination by the predominance of White peers in their social class.[79] The experience of discrimination can also reduce leukocyte telomere length and lead to worse health outcomes, even when controlling for other factors such as social class.[80] Recognizing the impacts of interpersonal and systemic racism and discrimination is crucial to addressing health disparities and working toward a more equitable healthcare system that supports individuals affected by weathering and allostatic load.

DIMENSIONS AND DEMOGRAPHICS OF DISPARITIES

Females

The historical discrimination against and exclusion of females from equal positions of power has had a profound impact on their surgical disparities. Females were denied the right to vote in the United States until 1920 as well as the right to have sovereign control over civic matters or their bodies, with risk of sexual violence and exploitation being part of the legacy of colonial power in the United States and Canada. Historians have thoroughly documented how gendered violence—even the construction of gender—was a colonial project that continues to have modern ramifications.[81] Financial control was difficult because of such factors as gender pay and wealth gaps; females were not even legally allowed to own a credit card without husband approval until 1974 with the passage of the Equal Credit Opportunity Act. Various forms of gendered discrimination have also led to disparities in surgical care, with fewer female surgical providers leading to a lack of gender-specific insights and biases in treatment decisions. Indeed, an entire branch of study—feminist epistemology—is dedicated to the unique knowledge held by females, a knowledge that is lost in surgical fields dominated by males. Some surgical specialties (e.g., urology, neurosurgery, orthopedic surgery) have less than 15% female surgeons and even lower numbers of female faculty, despite females comprising more than half of medical school enrollment.[82,83] In the most comprehensive survey of surgical residents across the United States, 65% of female residents reported gender discrimination, and 20% reported sexual harassment, with attendings being the most frequent sources of the latter.[84] Again, such forms of violence, as referenced earlier, have firm roots in our colonial history and thus shape the forms of knowledge created and disseminated in masculine spaces. Increased exposure to abuse and mistreatment leads to increased rates of burnout, suicidal ideation, and attrition among females in surgery.[85] Higher attrition by female surgical residents leads to worse outcomes for all patients because having a female surgeon has been shown to reduce postoperative short- and long-term outcomes, including a 25% reduction in mortality for all patients, highlighting the importance of gender diversity in surgical specialties. Stated differently, both females and males operated on by females have a 25% lower postoperative mortality rate, whereas females operated on by males have a 25% higher risk of postoperative mortality for reasons that require further investigation.[86,87] Such studies raise the question, often posed in a similar vein to feminist epistemology, about what important forms of gendered knowledge can do for patients.

In the United States, disparities in surgical care for females, especially concerning increasing maternal mortality rates for females of color, underscore gendered racism, systemic biases, and unequal healthcare access.[88] In fact, non-Hispanic Black females are three to almost four times more likely to die while pregnant or within 1 year postpartum than their non-Hispanic White and Latina counterparts. These disparities intersect with broader structural inequities, affecting health outcomes for marginalized groups.[89] Reproductive rights, especially to abortion, were established in 1973 but overturned with the *Dobbs* decision in June of 2022.[90,91] Since Roe v. Wade was overturned, rape has already resulted in 64,565 pregnancies in 14 US states with near-total abortion bans, according to a January 2024 study.[92] Efforts to address these disparities involve improving access to quality prenatal care, raising awareness of maternal health issues, combating biases within healthcare systems, and ensuring reproductive healthcare access for all individuals. Other surgical disparities for females persist, including access to timely oncologic treatment, timely transport to trauma centers, access to minimally invasive approaches to surgery, and more.[93–95] Research has identified antifemale bias in medical education, textbooks, and Medicaid reimbursement rates, which are significantly lower for surgical procedures specific to females.[96] This structural sexism, analogous in some ways to structural racism, detrimentally affects health outcomes for both females and males. Colonial constructions of masculinity and patriarchy continue to exert their influence on societal health by directly undermining the autonomy of females and their physical health. Given what we know about the critical nature of feminist epistemology for broader societal well-being, this systematic undervaluation of feminine life may lead to broader structural inequality, safety deprivation, and poor population health for all genders.[97] Recognizing and dismantling these barriers is crucial for achieving a future in which all females have equitable access to safe and effective surgical, reproductive, and peripartum care, respecting autonomy and dignity of females as both patients and providers.

Lesbian, Gay, Bisexual, Transgender, Queer, Plus (LGBTQ+) Patients

Surgical disparities are prevalent within the LGBTQ+ community, especially in accessing gender-affirming surgery that is crucial for transgender and gender-diverse individuals. Limited health insurance coverage and inadequate knowledge among healthcare providers are key barriers to these operations, leading to financial burdens and restricted access to qualified surgeons. Research shows that gender-affirming operations significantly improve mental well-being, alleviate gender dysphoria, and prevent suicidal ideation, including in the long term, emphasizing the importance of addressing disparities in access to this surgical care within the LGBTQ+ community.[98] Regret after gender-affirming surgery is 1%, with satisfaction rates of 93%, well exceeding the rates for similar operations in the non-LGBTQ+ population, including in adolescents.[99–101] Unique surgical considerations range from soft tissue infections to access to bariatric surgery, oncologic surgery, and laryngology.[102]

Beyond gender-affirming operations, LGBTQ+ individuals encounter obstacles such as discrimination and delayed care in various surgical areas, including cancer and reproductive healthcare. Surgeons must address these disparities by advocating for expanded insurance coverage, enhancing education on LGBTQ+ healthcare, and fostering inclusive healthcare environments. Hate crimes, violence, and homicides against intersectional transgender identities are a concern for trauma surgeons, with many homicidal hate crimes reporting erroneous gender identity in formal, federal databases.[103] Antitransgender legislation is strongly associated with suicide-related Internet searches in states with a high LGBTQ+ population density.[104] Efforts to protect human rights and dismantle barriers to care are essential in ensuring equitable access to safe and affirming surgical care for all LGBTQ+ individuals, promoting better health outcomes and overall well-being.

Surgical Disparities and Geographic Factors

Access to surgical care is significantly influenced by geographic factors, often further exacerbated by socioeconomic constraints, thus contributing to disparities among different regions. Two key factors affecting surgical disparities are the lack of access to care and the presence of trauma deserts, particularly in impoverished communities. These factors are themselves linked to racial capitalism in that the pattern of distribution of healthcare resources is shaped by perceived racialized and spatialized value. In other words, marginalized Black, Indigenous, and rural communities are not viewed as profitable to US healthcare interests; thus, these communities generally lack critical access to healthcare.

Lack of Geographic Access to Surgical Care

In rural and remote regions with high poverty rates, there is a heightened concentration of surgical disparities. Factors such as a shortage of qualified healthcare professionals, financial constraints, and difficulty attracting providers to underserved areas contribute to limited access to comprehensive surgical services. Consequently, individuals in these communities experience prolonged wait times for surgical procedures or are forced to travel considerable distances to receive necessary care, resulting in delayed or compromised treatment outcomes. Even in rural areas with relative affluence, concerning trends for surgical specialties treating cancer, for example, demonstrate a reduction of specialist presence over time.[105] The unique situation of rural surgical care has even led to the creation of the American College of Surgeons (ACS) Rural Hospital Surgical Verification and Quality Improvement Program to address these disparities.[106] In general, a free-market, private-based approach has shown itself inadequate to rationally organize the healthcare system based on population needs, largely because of the corporate obligation to increase profits and ensure a return to shareholders.[107]

Trauma Deserts

Poverty-stricken communities in both urban and rural areas face challenges in accessing trauma centers and emergency surgical services, contributing to disparities in surgical care. Residents in rural regions are at a higher risk of mortality after traumatic injuries compared with urban counterparts, with over 30 million Americans lacking trauma care within an hour of injury.[108,109] These areas, known as *trauma deserts*, lack nearby trauma centers, leading to delays in lifesaving interventions and poorer patient outcomes.[110] Limited access to trauma care resources as a result of poverty exacerbates disparities, affecting the quality of care and worsening outcomes after traumatic incidents. Strategic opening of trauma centers within trauma deserts reduces transport times and disparities in access.[111]

Impact of Poverty and Economic Inequality on Surgical Disparities

Poverty contributes significantly to surgical disparities, particularly affecting disadvantaged communities and individuals with unstable employment. Limited financial resources impede access to essential healthcare, including operations, because of the high costs involved in evaluations, procedures, postoperative care, and medications. Cesarean sections, for example, can cost more than $35,000, with a 28-fold increase in observed to expected cost ratios across the United States.[112] Economically disadvantaged individuals often delay or forgo necessary operations, leading to deteriorating health outcomes and perpetuated disparities. Additionally, precariously employed individuals and gig economy workers, lacking stable income and adequate benefits, face challenges in affording operations, prompting delayed care and potential long-term healthcare cost escalations.[113] The comprehensive review “The Surgery of Poverty” sheds light on an unseen population of impoverished individuals surviving amid societal affluence, often invisible despite living on the brink of financial crisis.[114]

Poverty and economic inequality both worsen surgical disparities but in distinct ways. Poverty restricts individuals’ healthcare access, particularly access to surgical care, as a result of financial limitations. Those in poverty encounter obstacles like insurance unaffordability, transportation issues, and limited quality healthcare options. Unhoused individuals are frequently exposed to violence and experience a higher rate of complications and mortality after trauma.[115] The surgical literature lacks clear definitions and research on how housing status influences optimal surgical care, particularly in the intraoperative phase, highlighting the need for standardized recording of housing status and further exploration of vulnerabilities specific to homeless individuals for better care.[116] Economic inequality relates to the broader societal distribution of wealth and resources. High levels of economic inequality can lead to disparities in healthcare access and outcomes across different socioeconomic groups, and economic inequality is a larger predictor of adverse outcomes, including homicide, than absolute poverty.[117]

In the United States, income and wealth inequality rank among the highest globally, with disparities persisting notably among racial groups as a result of historical injustices such as slavery and discriminatory economic policies. Medical issues are a leading cause of bankruptcy, with about 66.5% of cases attributed to costly healthcare or income loss from health-related challenges, affecting approximately 530,000 families annually.[118] Previous research indicates that most medical debtors are well-educated homeowners with middle-class occupations, and the majority have health insurance.[119] Solutions proposed to tackle income inequality involve implementing progressive income tax systems, taxing ultra-high-income individuals, instituting inheritance levies, increasing the minimum wage, bolstering labor rights, and enhancing educational opportunities.

Poverty hinders individuals from accessing essential surgical care, whereas economic inequality can lead to broader systemic disparities in healthcare outcomes, emphasizing the need to address both poverty and economic inequality to combat surgical disparities and ensure equitable healthcare for all.

Surgical Disparities in Immigrant and Refugee Populations

Surgical disparities extend beyond geographic and socioeconomic factors, affecting marginalized populations such as immigrants and asylum seekers. These individuals often face unique challenges that contribute to disparities in accessing surgical care. As with other racialized groups, racial capitalism within the United States systematically devalues the lives of immigrant and refugee populations, as seen in their relative inability to access healthcare, including surgical care.

Barriers to Access

Immigrants and asylum seekers face various obstacles in accessing surgical care, including language barriers that hinder effective communication with healthcare providers and cultural differences that complicate navigating the healthcare system. An asylum seeker is someone who leaves their home country and seeks international protection in another country due to displacement, possibly from war; upon acceptance in the new country, the asylum seeker transitions into a *refugee*, a distinction often misconstrued with terms like *illegal immigrant*. Legal restrictions, such as lack of health insurance or limited access to public healthcare programs, present significant challenges for these populations. Undocumented immigrants (asylum seekers become undocumented immigrants when the host country rejects their asylum claim), fearing deportation or legal repercussions, may present late (or not at all) for surgical or clinical services, as occurred during the COVID-19 pandemic.[120] Racism and xenophobia, for example, as seen regarding Asian and Asian American populations during COVID-19, can detrimentally affect health outcomes.[121] Unique to the US-Mexico border wall, the increase in height from 10 to 30 feet has led to a simultaneous increase in falls, hospital costs, injury severity, and mortality, representing a public health crisis.[122–124] Healthcare systems must address these disparities by promoting inclusivity, providing language assistance, ensuring cultural competency, and ensuring protection of human rights to guarantee equitable access to surgical care for all, irrespective of immigrant status or racial background.

Trauma and Mental Health Considerations

Immigrants and asylum seekers, having endured displacement, conflict, and persecution in their home countries, often bear the scars of physical injuries, torture, or mental anguish, necessitating surgical care for healing. Particularly difficult is establishing trust with refugee patients who have experienced torture with physician complicity in human rights violations.[125] Polarizing rhetoric in recipient countries can lead to psychological distress and place asylum seekers at risk of preventable morbidity and mortality and delayed recovery after migration.[126] Despite these urgent needs, barriers to specialized trauma treatment can mean delayed operations or inadequate care, worsening their already traumatic experiences. Additionally, untreated chronic illnesses from a lack of proper healthcare in their home regions may lead to surgical requirements, risking further health complications due to disparities in timely access to necessary procedures. Surgeons can play an important role in the medical forensic evaluation of asylum seekers, specifically in cases of torture, which can support the legal case of applicants.[127]

Mass Incarceration and Surgical Disparities

Understanding the complex roots of American mass incarceration is vital for addressing this multifaceted public health crisis and understanding mass incarceration as its own social determinant of health. Legal, economic, and political forces, tied to the legacy of slavery and Indigenous population displacement and compounded by labor exploitation and systemic racism, spurred a dramatic rise in US prison populations from the 1970s onward, peaking in 2009. The United States has the highest number of incarcerated human beings in the world, disproportionately incarcerating people of color, such as Indigenous, African American, and Latino populations.[128] One in three Americans who are Black will be arrested in their lifetimes.[129] Incarceration has been found to be a risk for future community violence.[130] This increase was not a straightforward response to crime but a result of policies responding to and exacerbating social and health issues, including mental illness and substance use disorders, particularly within African American communities, branding mass incarceration as the "new Jim Crow."[43] There is evidence that this system of mass incarceration, implemented during the Nixon era, was deliberately created to disrupt the civil rights and peace movements, even before the "War on Drugs."[131] Mass incarceration parallels the institution of slavery because both are economic systems that profit from the labor of enslaved Black persons. The modern prison-industrial complex benefits economically from the labor of inmates, who are often paid extremely low wages or no wages at all for their labor. Refusal to work can lead to solitary confinement, recognized as a form of torture. This has been criticized as a form of modern-day slavery, especially under the 13th Amendment of the US Constitution, which allows involuntary servitude as a punishment for crime.[15] Ensuring that private, for-profit prisons are maintained to capacity is another mechanism by which mass incarceration generates enormous profits. Both systems have historically served to legally, politically, and socially disenfranchise these communities, perpetuating cycles of family separation, dehumanization, and economic inequality. These parallels underscore deep systemic issues in the criminal justice system that reflect and extend the injustices of slavery into the present day. Similar patterns are being seen with family separation and incarceration of asylum seekers at the US-Mexico border and beyond.

Once previously incarcerated persons are liberated from their sentence, reintegration back into society is extremely difficult, increasing the risk of reincarceration. For example, many formerly incarcerated individuals cannot vote as a result of voter disenfranchisement in many states, cannot work because federal law does not prohibit employers from inquiring about criminal records, cannot obtain adequate levels of food because public benefits such as the Supplemental Nutrition Assistance Program are denied, and cannot further their education because loans, grants, and scholarships are also denied. Family separation is not uncommon because publicly funded housing is often denied to individuals with a criminal record and their family members. Having a parent who has been incarcerated during a person's childhood is a risk factor for firearm injury, with significant negative health impacts on children and female partners of incarcerated males, thus affecting entire communities.[132,133] Surgical illness is poorly documented in the prison system, with preventable surgical pathology being a not-infrequent cause of death—for example, it was the cause of death of 25% of inmates in one cohort from Florida.[53] Since its peak in 2009, the US prison population has prompted the Department of Health and Human Services to recognize incarceration as a determinant of health disparities, leading to calls from public health experts for structural reforms, especially in light of the COVID-19 pandemic and increasing research linking incarceration to health inequalities.[134]

Intersectionality and Surgical Disparities

Coined by Dr. Kimberlé Crenshaw, a University of California, Los Angeles (UCLA) law professor in 1989, the term *intersectionality* refers to the intersection and interconnectedness of identities such as race, gender, ethnicity, sexuality, and disability. Intersectionality is pivotal in comprehending and addressing surgical disparities, recognizing that individuals from marginalized and intersecting identities can face compounded obstacles, both exponentially and simultaneously, based on race, sex, sexual orientation and gender identity, social class, and others. Examples of these disparities are seen among patients with cancer and those suffering from traumatic injuries. Compared with White females with breast cancer, Black females with breast cancer have a 40% higher mortality rate despite having a lower incidence rate, and breast cancer among Latinas is the leading cause of death despite this group having a lower incidence rate.[135] Access to care, lack of health insurance, barriers to screening, delays in diagnostic workup, and presentation with a more advanced disease stage at initial diagnosis all contribute to these disparities. Individuals with disabilities or reduced abilities also face surgical disparities in treatment of lung and breast cancer.[136,137] Identified barriers to screening contributing to these inequities include a lack of accessibility for parking, interior/exterior routes, and rooms inclusive of restrooms and a lack of functional, accessible equipment in screening facilities.[121] Yet there is a paucity of data addressing the role of the intersection of race/ethnicity, sex, and disabilities on surgical disparities and outcomes. Among patients suffering traumatic injuries, the disparities are pervasive. In the prehospital trauma system, one study found that critically injured female patients are less likely to be transported to verified trauma centers when compared with their male counterparts despite data showing that transport of trauma patients to verified trauma centers is associated with a significant reduction in preventable deaths and injury-related mortality.[138] Other studies reveal disparities in trauma outcomes and discharge to rehabilitation facilities based on race and insurance status, underscoring the need for targeted interventions, such as improving healthcare coverage and addressing implicit biases.[139–141] Acknowledging and measuring disparities through an intersectional lens is crucial to developing tailored interventions for marginalized communities with multiple and interlocking identities and promoting diversity and equity in surgical training and leadership roles to mitigate intersectional barriers and achieve healthcare equity. Using a framework for intersectionality in research on surgical disparities has been proposed to mitigate inequity.[142–145]

UNDERLYING CAUSES OF DISPARITIES IN SURGERY

When exploring surgical disparities, it is crucial to examine the underlying causes that contribute to these inequities. Disparities can arise from individual, institutional, and systemic causes and factors. It is important to note that these various levels interact with and determine one another—for example, systemic racism shapes institutional resources and thus leads to inequalities in education and health literacy among racialized groups relative to White people.

Individual and Provider Factors

Surgical disparities arise from various individual factors affecting both patients and providers. Socioeconomic status, limited health literacy, and cultural differences can hinder access and decision-making in surgical care. Provider biases, especially implicit biases, significantly influence treatment decisions, potentially leading to delayed diagnoses and disparities in pediatric organ allocation for transplantation, postoperative care, and other outcomes.[146] The sentinel *New England Journal of Medicine* study by Schulman et al. in 1999 demonstrated that bias caused Black females with chest pain to be referred significantly less frequently for cardiac catheterization compared with White males.[147] Similarly, persistent implicit bias has also been well documented by Haider et al. in surgery and in medical students. Internalized implicit bias may also manifest in providers, often called *imposter syndrome* or *stereotype threat,* where the predominant system and culture of surgical providers generate feelings of exclusion in individuals not belonging to the majority group.[148]

Bearing witness to the system of structural violence and racism that leads to direct violence can also lead to increased burnout or compassion fatigue in providers.[149,150] Cultural competency among healthcare providers is vital to understanding and respecting diverse patients' cultural beliefs and practices.[151] Lack of cultural competency can lead to miscommunication and hinder the delivery of surgical care, especially for marginalized populations facing cultural barriers. Enhancing cultural competency can facilitate trust building, improve patient-provider communication, and ensure culturally sensitive care, underscoring the importance of a diverse and inclusive surgical workforce aligning with patient communities for better healthcare outcomes.[152] In fact, in one narrative review, 93% of medical patient experiences were found to be neutral or improved with concordance in terms of race, sex, and intersectionality. Other research has begun to identify outcome metrics, ranging from racial concordance for neonates and neonatologists (58% reduction in mortality) to time to administration of antiretrovirals (longer in Black patients treated by White providers, but not vice versa) and the previously mentioned gender concordance for surgical outcomes (25% reduction in mortality with female surgeons, for patients of all genders).[87,153,154] This speaks to the crucial importance of having diverse professional surgical workforces that are reflective of the communities they serve.

Institutional Factors

Various institutional factors contribute to surgical disparities, such as unequal access to healthcare in underserved regions and for those lacking insurance, alongside socioeconomic disparities affecting financial resources and health literacy. Institutional causes of healthcare disparities pertain to specific healthcare structures, policies, and biases affecting access and treatment, including resource limitations, reimbursement policies, eligibility criteria, and biases within healthcare settings. Access to healthcare seems to affect disparities in treatment outcomes, as shown in studies analyzing colon cancer and other surgeries. Factors like hospital volume, location, and access to quality-seeking facilities play crucial roles in determining outcomes, with disparities in care being observed based on race and access to high-volume hospitals.[2] Institutional biases, cultural barriers, and health policies all affect disparities among racial and ethnic minoritized groups, exacerbated by fragmented healthcare structures leading to inequities in surgical outcomes. Moreover, systemic obstacles faced by underrepresented individuals in medicine, including insufficient mentorship, unconscious biases, and a less inclusive training environment, have led to increased unintended attrition rates in surgical fields of racialized trainees and hinder success in surgical training programs due to stress and isolation resulting from cultural and socioeconomic differences.[155]

Systemic Factors

Systemic factors encompass structural and policy-related barriers leading to unequal healthcare access, manifested in limited availability of surgical services for marginalized communities, the need to travel farther for specialized care, or generalized exclusion because of structural racism and discrimination against our patients, their families, and communities.[5] Systemic causes involve broader social, economic, and political elements shaping healthcare systems, including socioeconomic disparities, racial inequalities, and systemic biases influencing healthcare outcomes. Also described as *structural violence*, this is the harm caused by societal structures, institutions, and policies that restrict individuals or groups from fulfilling basic human needs, perpetuate inequalities, and hinder opportunities for progress, often affecting marginalized populations.

TACKLING SURGICAL DISPARITIES: A STRATEGIC FRAMEWORK

Surgeons have had a longstanding interest in addressing surgical disparities through measured actions to reduce, eliminate, or reconcile injustices with restorative justice. Building on the earlier work of Haider et al., the previous "patient-provider-systemic factors" model used to approach surgical disparities, Torain et al. introduced the additional domains of clinical care/quality and postoperative care and rehabilitation. They further highlighted the impact of these domains across the patient care continuum, influenced by preoperative (insurance coverage, hospital access), intraoperative (hospital/provider practices), and postoperative (morbidity, mortality, rehabilitation services) factors.[156] A 2015 research summit was also organized by the ACS and the National Institutes of Health (NIH), which focused on factors like clinician behavior, access to care, and postoperative rehabilitation, emphasizing priorities such as improving patient-clinician communication and assessing long-term intervention effects to reduce surgical disparities.[157] Shortly thereafter, Britt et al. highlighted the urgent need for standardized quality indicators and the development of disparities-sensitive metrics to address and monitor inequities in surgical access and outcomes.[158] There was still a need, however, to investigate the root causes of surgical disparities for effective interventions, with surgeons over the years engaging in advocacy and activism in parallel with society at large.[159] A comprehensive strategy involving healthcare workers, community members, patients and families, academic surgeons, and affected organizations and individuals is essential to combat these inequities at various intervention points. Such collaborative, multilevel research efforts, informed by community and patient perspectives within a historical context, are vital for mapping and addressing priority intervention areas.

A useful conceptual framework for addressing surgical disparities encompasses four critical components: mechanisms for identification, reduction, elimination, and healing from the harm engendered by disparities, in conjunction with dismantling the underlying societal structures that contribute to their perpetuation.

Identifying Disparities

Identifying and documenting surgical disparities involves the use of various methods, such as analyzing demographic data, patient outcomes, and healthcare utilization patterns, focusing on factors such as race, ethnicity, socioeconomic status, sex, and geography. Cross-sector collaboration among healthcare institutions, government agencies, community organizations, and researchers enhances data collection and analysis, fostering the sharing of information, the creation of standardized metrics, and the implementation of strategies to effectively address disparities. Measuring surgical disparities includes capturing quantitative health equity metrics ranging from board certification, standardized clinical guidelines, and equity metrics to the social determinants of health, such as food insecurity. Place-based composite scores, including social class (e.g., the National Cancer Institute Socio-Economic Index or the Firearm Violence Vulnerability Index), are increasingly being used and validated in cancer, trauma, and other domains of surgery.[133,160] Qualitative research is an imperative tool to capture patient-centered voices on satisfaction, bias, perceived quality, and decision-making empowerment.[161] New multidisciplinary approaches that use the expertise of affected individuals, such as community-based participatory research, are another tool to identify surgical disparities. This should be considered the gold standard of research, by encouraging participation of affected communities in the directing of the research about them.[162] When considering patient factors like comorbidities, preferences, and health literacy, surgeons can tailor recommendations in the perioperative period and assess access to care, postoperative services, and barriers to address disparities comprehensively.

Recognition of healthcare equity as a vital quality measure is increasing, supported by organizations like The Joint Commission (TJC) and Centers for Medicare and Medicaid Services (CMS).[163,164] Despite limited use in hospital benchmarking, the emphasis on identifying health equity metrics, including equity stratifiers, signifies its growing importance.[165] Integrating equity metrics into verification programs, establishing inclusive cultures in healthcare institutions, and collaborating with community groups while considering social determinants of health can drive meaningful change. Evaluating health equity through trauma verification processes focusing on leadership commitment, infrastructure, and equity processes aligns with efforts to reduce healthcare disparities mandated by TJC and the CMS (Box 14.2).

In establishing institutional clinical objectives for health equity, key steps include developing targeted goals within quality improvement programs to address health disparities and outcomes for marginalized populations. Creating a comprehensive dashboard to monitor equity metrics across clinical departments, analyzing health equity outcomes along the care continuum, and enhancing electronic health records with data on social determinants are vital initiatives to identify areas for improvement and reduce disparities in healthcare.[166] These actions enable institutions to focus on health equity, drive interventions, and advance toward eliminating healthcare disparities.

Reducing and Mitigating Disparities

To reduce surgical disparities, several strategies can be implemented. First, programs and initiatives aimed at increasing access and quality of care are essential. These can include, as examples, improving transportation options for patients, enhancing financial assistance programs, and increasing the availability of clinics and healthcare facilities in underserved areas. Second, policies can be put in place to standardize care delivery and reduce variation in outcomes. This can involve implementing evidence-based

BOX 14.2 The Four-Pronged Approach to Identify, Reduce, Eliminate, and Heal Surgical Disparities

1. **Identify disparities:** Analyze demographic data, patient outcomes, and healthcare utilization patterns, focusing on factors such as place-based risk factors, using novel research methods such as qualitative and community-based participatory action research.
2. **Reduce disparities:** Create programs and initiatives aimed at increasing access and quality of care. Policies can be adopted to standardize care delivery and reduce variation in outcomes. Cultural and structural competency courses are important to provide patient-centered care.
3. **Eliminate disparities:** Promote inclusive surgical leadership that embraces psychological safety; a diversity of ideas is key. Leadership can then influence policy to adopt structural changes such as universal health coverage and labor protections.
4. **Heal disparities:** Apply the reparations approach of acknowledgment, apology, redress, compensation, and system change in response to recognized disparities with legal advocacy and policy change.

guidelines and protocols, improving data collection and analysis, and ensuring that healthcare facilities adhere to best practices. This is particularly important to reduce preventable morbidity and mortality because high social class is not protective against implicit bias or racism and, in fact, may worsen implicit bias or racism.[167,168] Additionally, education and training can play a crucial role in combating healthcare provider biases. By raising awareness about unconscious biases, cultural humility, and the importance of equitable care, healthcare providers can be better equipped to deliver unbiased and patient-centered care to all individuals, regardless of their race, ethnicity, or socioeconomic status. Hisam et al. have identified potential mitigation strategies for surgical disparities across four primary themes: condition-specific targeted strategies, enhanced integration of quantitative metrics, fostering effective doctor-patient communication, and promoting cultural humility within healthcare settings.[156] Overall, a holistic approach involving these strategies can help reduce and mitigate surgical disparities.

In addressing surgical disparities, enhancing access to training and leadership positions in surgery for underrepresented, racialized minorities is crucial. Initiatives focusing on diversity and representation in the surgical field through scholarships, mentoring, and outreach programs can help bridge gaps and support individuals from underrepresented backgrounds in pursuing successful careers in surgery. For instance, programs like the University of Chicago Pritzker School of Medicine Phoenix curriculum, designed to reduce economic barriers and eliminate medical school debt, can contribute to lessening disparities by providing financial support and opportunities for individuals facing economic challenges to enter the medical field.[169] This increased diversity can lead to more culturally competent and equitable surgical care, benefiting a wider range of patients.

It is crucial to cultivate inclusivity in surgical training programs by fostering diversity and offering support to underrepresented individuals. This includes providing mentorship, sponsorship opportunities, and implicit bias training to faculty and staff to ensure fair evaluations and promotions. Encouraging equal access to leadership positions for underrepresented minority surgeons involves establishing action-based diversity committees, promoting mentorship and sponsorship, operating within an antidiscriminatory framework, and offering professional development resources within surgical organizations.[170] By expanding opportunities for underrepresented individuals in surgery, we can enhance diversity and representation, ultimately improving the quality of care while ensuring equal opportunities for all aspiring surgeons, regardless of background and historical barriers to training.

Competency Training

Cultural and structural humility with action toward structural justice is an approach to address provider-level causes of surgical disparities.

Cultural humility. Cultural humility is essential in mitigating surgical disparities by enabling surgeons to provide effective and patient-centered care. Understanding diverse cultural values and needs, including addressing unique challenges and disparities among different groups, allows for tailored healthcare solutions. Culturally humble and sensitive surgeons can nurture trustful doctor-patient relationships, enhancing patient satisfaction and treatment adherence. Surgeons can develop cultural competency through formal education and training programs, continuing medical education credits, and hands-on cultural immersion experiences. Engaging in mentorship, pursuing self-education, and actively seeking feedback can further enhance their understanding and application of culturally competent care. Participation in community events and direct engagement with diverse patient populations provide practical insights and promote empathy, leading to more personalized and effective healthcare delivery.[151] As an example of community-engaged healing, Dr. LJ Punch's Bullet Related Injury Clinic ("The BRIC") employs a novel model wherein a multidisciplinary team collaborates with patients, families, and communities to address all aspects of bullet-related injuries, emphasizing holistic healing and trust building. Rather than viewing the community as a passive stakeholder, Dr. Punch positions it as the central focus of the healing process.[171]

Structural competency and justice. Integrating structural competency and justice into healthcare enables providers to address the root social, economic, and political causes of surgical disparities by recognizing and advocating for systemic changes that promote equitable access to care. This approach, which includes training in understanding and counteracting systemic injustices, is essential for establishing a more equitable healthcare system that acknowledges and addresses the broader determinants of health and surgical outcomes.[172–174]

Eliminating Surgical Disparities

The ACS Metrics for Equitable Access and Care in Surgery Group (MEASUR) project, funded by the NIH and led by the ACS, aims to identify surgical care disparities and offers pathways for their elimination. Its goal is to ensure equitable healthcare access for all surgical patients. Using a systematic review, the authors defined surgical access, identified measures of disparities, and created a model to address them. Measures were categorized into 14 surgical subspecialties and 6 disparity domains. This work provides a framework for addressing disparities in surgical care, validating novel metrics, and tailoring interventions based on specific needs for their targeted elimination.[158,175]

Promoting inclusive leadership and policy development, which involves including individuals from diverse backgrounds in decision-making roles, allows healthcare organizations to address the unique needs of marginalized communities. Inclusive leadership supports the creation of wide-ranging policies that can each identify, reduce, and eliminate surgical disparities. The Michigan Promise is an initiative by the University of Michigan's Department of Surgery aimed at promoting diversity, equity, and inclusion through comprehensive strategies that encompass recruitment, leadership development, research on health disparities, and education and training to improve surgical care and outcomes.[176,177] Inclusivity can also be extended to diversifying healthcare provider teams, thereby enhancing cultural humility and patient satisfaction. Additionally, a commitment to continuous research and the use of best practices is crucial in addressing disparities. By conducting targeted research on surgical disparities, healthcare systems can pinpoint underlying causes and implement evidence-based interventions. Adapting practices based on current evidence and best practices is essential for sustained progress in reducing disparities.

Earlier in the chapter, we described how the root causes of health inequity and surgical disparities in the United States are deeply embedded in historical and current inequities across various social determinants of health, shaped by institutional, societal, and policy factors. These disparities have influenced various key factors affecting health, such as education, income, employment, healthcare systems, housing, the environment, transportation, social conditions, and public safety. W.E.B. DuBois concluded in 1906, in reference to health inequities experienced by African Americans, that “the present difference in mortality seems to be sufficiently explained by conditions of life.”[178] Dr. DuBois, in fact, lost his 2-year-old son Burghardt to a treatable infection (nasopharyngeal diphtheria) because “no White physicians [were] willing to treat a Black child.” Without a concerted effort by surgeons and physicians to address these structural inequities, eliminating disparities will become impossible, and efforts will be focused on identifying, measuring, and mitigating disparities only. Disentangling the influence of corporate interests on government policies over average citizens or mass-based interest groups is crucial to centering social and economic policies on the well-being of patient populations and adherence to a democratic structure.[179]

For example, universal healthcare provides timely and accessible surgical services for all individuals, regardless of socioeconomic status, race, or other identities, and ensures access to necessary surgical interventions.[180–184] Other system-level changes include building patient-centric trauma centers in trauma deserts alongside community activists and families, as exemplified by the University of Chicago Medicine Trauma Center of the South Side of Chicago.[185] Many current lessons on equity in healthcare can be recalled from past activist movements such as the Black Panther Party or the Young Lords, which fought together for justice and equality in Black and Puerto Rican communities, respectively. Together with the Young Patriots, created to support young, White migrants from the Appalachia region who experienced extreme poverty and discrimination, the three groups formed the Rainbow Coalition, based in Chicago. The Rainbow Coalition’s antiracist, multicultural, working-class movement focused on community uplift with free breakfast programs for children, free health clinics and sickle cell screening, clothing drives, and monitoring of police activity. The three groups were street gangs that converted into a civil and human rights organization while facing continuous government repression.[186] Drawing inspiration from historical movements like the Rainbow Coalition, today’s efforts to combat surgical disparities emphasize the importance of equitable healthcare access and address systemic inequalities, working toward more just and inclusive surgical care practices.

Eliminating surgical disparities necessitates long-term strategies focusing on the social determinants of health, inclusive leadership, continuous research, and best-practice adaptation. Implementing systemic changes can foster an equitable, inclusive healthcare environment, leading to improved outcomes for all patient populations.

Healing Disparities

Acknowledging, apologizing for harm, providing redress, and achieving closure are crucial steps in transitioning from measuring to healing healthcare disparities. Reparations (the formal recognition and practice of healing historical and ongoing harms of marginalized groups through various material and symbolic actions) play a significant role in rectifying historical injustices that have contributed to health disparities and surgical inequities. According to Bassett and Galea, reparations can decrease health disparities in Black Americans by expanding resources, alleviating psychological stress, and paving the way for intergenerational wealth equality.[187] Himmelstein et al. found that reparations targeting racial wealth disparities could potentially reduce the life-expectancy gap between Black and White individuals by up to 100%, addressing health disparities rooted in historical inequities like slavery and discriminatory policies.[188] By addressing resource gaps and providing restitution through reparative measures, particularly for Indigenous and Black American communities, reparations can help reduce structural racism–related wealth gaps and alleviate health-damaging stress. The gender wage gap could be targeted for intervention as well. Reparations can thus have a substantial impact on mitigating societal inequities and improving population longevity. Furthermore, investing in reparations not only improves the present health outcomes of marginalized populations but also has a lasting impact by leveling the wealth playing field for future generations, ultimately reducing disparities in health outcomes. The Walter and Patricia Rodney Commission on Reparations explores the moral, legal, economic, historical, and political evidence for various global claims to reparations and redistributive justice.[189] By convening scholars and activists worldwide, the Commission aims to propose actionable reparations programs and provide guidance to policymakers and experts internationally.

Apology

Acknowledgment of civil and human rights violations by powers responsible can lead to apologies and consensus-building. Survivors have a necessity for equitable healthcare access, and apologies can aid in shifting focus from blame to constructive dialogue within the medical community and society at large, fostering unity to address surgical disparities and ensure fair and equal surgical care for all patients. This process enables societies to confront historical injustices, uphold values, and fulfill obligations to victims in the pursuit of a more equitable healthcare system.

Examples include:

1. In 2009, President Barack Obama signed the Native American Apology Resolution, formally apologizing to Native American tribes for past injustices and abuses by the US government; however, Indigenous leaders were not present for the apology.
2. Canadian Prime Minister Stephen Harper issued an apology in June 2008 to survivors of Canada’s residential boarding school system, leading to the Truth and Reconciliation Commission but no reparations.
3. President Bill Clinton issued a formal apology in 1997 to survivors and families affected by the Tuskegee Syphilis Study, acknowledging the harm, betrayal of trust, and ethical violations committed during the study.

Establishing a US truth and reconciliation commission is seen as vital for racial justice, acknowledging the historical trauma linked to slavery and racism in the country.

Compensation

Compensation through reparations is crucial in reducing surgical disparities because it acknowledges past injustices, provides monetary or tangible support to affected individuals or communities, and can help address systemic barriers by promoting access to necessary healthcare services for marginalized populations. This process can contribute to rectifying past wrongs, fostering trust, and working toward a more equitable healthcare system.

Examples include:

1. Native American Tribes: Over the years, several Native American tribes have received some compensation and land settlements for treaty violations and loss of tribal lands, facilitated in part by the Indian Claims Commission established in 1946.
2. Rosewood Victims: In response to the 1923 Rosewood massacre, Florida passed legislation to compensate survivors and descendants, offering direct payments, scholarships, and funds for a memorial as reparations for the destruction caused by a White mob to a predominantly Black town.

Reparations

Reparations can play a crucial role in reducing surgical disparities exacerbated by the racial wealth gap by providing financial resources to marginalized communities that have historically faced systemic barriers to healthcare access. By acknowledging and addressing past injustices through reparations, efforts can be made to level the playing field, promote equity in healthcare, and work toward closing the racial wealth gap within the context of surgical care.

Examples include:

1. After the abolition of slavery in Washington, DC, in 1862, the US government introduced reparations under the Compensated Emancipation Act to compensate slave owners for freeing their enslaved individuals. Notably, freed slave Gabriel Coakley used a legal loophole to receive similar reparations, enabling him to purchase family members, escape slavery, and establish a life of dignity. His family would become very successful in multiple endeavors, with his granddaughter, Dr. Lena Edwards, graduating as one of the first Black obstetrician-gynecologists in the United States.[190]
2. President Ronald Reagan's official proclamation in 1988 marked the enactment of the Japanese Internment Apology legislation, which provided financial reparations through the Civil Liberties Act to Japanese Americans imprisoned in camps during World War II.
3. In 2015, Chicago set a precedent with a reparations package addressing police torture under Jon Burge. This unique package includes up to $100,000 in financial compensation for each victim, integration of these cases into Chicago Public Schools' curriculum for educational awareness, the creation of a public memorial, the establishment of a counseling and support center on the South Side, and free tuition at City Colleges of Chicago for victims and their families. This holistic strategy aims not only to compensate but also to educate, honor, and heal, marking a significant city effort to right the wrongs of its past police misconduct.
4. Evanston, Illinois, launched its Reparations Program in 2019 to address the impact of historical redlining on the African American community, providing financial aid and resources to eligible residents affected by discriminatory housing practices. The program seeks to rectify systemic injustices that have hindered Black families' economic progress.
5. The California Reparations Task Force, established in 2020, is examining reparations for African Americans with ties to slavery, focusing on systemic racism and health impacts and proposing redress specifically for descendants of antebellum slavery. California seeks a comprehensive approach integrating health considerations to improve outcomes, address inequalities, and promote well-being and equity within marginalized communities. San Francisco's formal apology to African Americans in 2024 signifies a commitment to the ongoing reparations process and highlights the importance of "health reparations" initiatives like those targeting asthma and obstetrical and gynecologic disparities, emphasizing the need for measuring the medical and surgical impacts of reparations for long-term progress.

In the United States, there is no federal reparations program dedicated solely to descendants of enslaved individuals. Yet ongoing discussions and advocacy efforts persist to address historical injustices and systemic racism within Black communities. Although some local entities have offered gestures like scholarships and public apologies to acknowledge their links to slavery or discriminatory practices, the debate over comprehensive federal reparations remains a prominent topic in American society, with activists and scholars calling for broader initiatives to address lasting legacies of injustice.

Overall, reparations can be a critical step in a broader process of healing from historical trauma, addressing the contemporary consequences of past injustices, laying the groundwork for a more equitable future, and eliminating the racial wealth gap. They are an important multifaceted approach to address immediate financial burdens while also building long-term institutional and systemic support to eliminate surgical disparities, foster an equitable healthcare system for underrepresented communities, and provide redress for past and current harms.

Combination Approach: Legal Advocacy and Policy Change

Legal advocacy is a contemporary tool to address surgical disparities. Medical-legal partnerships (MLPs) operate at the intersection of healthcare and legal services to identify and mitigate social issues, advocating for policy change and providing reparations where necessary. Specific initiatives within MLPs, such as assisting trauma patients with health-harming legal needs and working with hospital-based violence intervention programs, contribute to reducing surgical disparities by doing the following:

- Addressing social determinants of health
- Improving access to care
- Advocating for policy changes
- Supporting employment and income stability
- Enhancing patient compliance and follow-up
- Educating healthcare providers

MLPs offer a comprehensive strategy to mitigate legal and social obstacles in healthcare, promoting more equitable healthcare outcomes and reducing surgical disparities on a structural level through legal action.[191,192]

Health professionals working in the equity domain have recognized the dramatic impact that sweeping legislation and policy implementation can have on the health of populations. For example, the $1.9 trillion American Rescue Plan Act of 2021 initiated during the COVID-19 pandemic significantly reduced racial disparities and advanced health equity for low- and middle-income Americans in four major ways: (1) reducing child poverty, (2) closing gaps in medical care, (3) investing in community health, and (4) addressing social contributors to health, such as food insecurity, childcare, early education, emergency housing assistance, transportation, and environmental justice.[193,194] This economic impact payment program was deeply popular across the political spectrum and speaks to the importance of political will in addressing health disparities.

CONCLUSION

Addressing surgical disparities within marginalized communities, particularly among racialized and economically disadvantaged individuals in the United States, is essential to prevent recurring inequities leading to avoidable morbidity and mortality. Embracing antiracism frameworks to combat systemic racism and discrimination is crucial for achieving equitable healthcare outcomes. Physician, epidemiologist, and antiracism activist Dr. Camara Jones reminds us that achieving health equity involves valuing all individuals equally, rectifying historical injustices, and providing resources based on need.[194] Surgeons can play a dual role by implementing practice guidelines to address inequities in surgical care downstream and addressing and rectifying the structural injustices that contribute to healthcare disparities upstream. Surgeons can contribute by consciously creating inclusive environments for historically marginalized groups; disaggregating racialized data; fostering community partnerships; advocating for reparations; engaging in action for structural change, for example, separating health insurance from employment; creating a system of universal healthcare; ensuring basic labor standards; improving conditions for incarcerated individuals; and more. Together, surgeons must ultimately work toward the assurance of the condition of optimal health for all individuals, emphasizing the importance of valuing the collective human rights of all populations equally over the importance of profit generation. Implementing these recommendations will facilitate a more resilient and equitable public health system, eliminate the causes of surgical disparities, and safeguard the well-being of all our patients.

Bailey ZD, Feldman JM, Bassett MT. How structural racism works—racist policies as a root cause of U.S. racial health inequities. *N Engl J Med*. 2021;384(8):768-773.

The systematic disinvestment in public and private sectors within segregated Black neighborhoods has resulted in underresourced facilities with fewer clinicians, which makes it more difficult to recruit experienced and well-credentialed primary care providers and specialists and thereby affects access and utilization.

Bailey ZD, Krieger N, Agenor M, Graves J, Linos N, Bassett MT. Structural racism and health inequities in the USA: evidence and interventions. *Lancet*. 2017;389(10077):1453-1463.

The term structural racism refers to the totality of ways in which societies foster racial discrimination through mutually reinforcing inequitable systems (in housing, education, employment, earnings, benefits, credit, media, healthcare, criminal justice, and so on) that in turn reinforce discriminatory beliefs, values, and distribution of resources, which together affect the risk of adverse health outcomes.

Chen JC, Obeng-Gyasi S. Intersectionality and the surgical patient: expanding the surgical disparities framework. *Ann Surg*. 2022;275(1):e3-e5.

Intersectionality centers on the concept that social categorizations are interconnected rather than separate entities, emphasizing the combination of privileged and marginalized social structures as having a synergistic effect on behaviors that cannot be accurately characterized by simply "adding up" the identities.

Haider AH, Dankwa-Mullan I, Maragh-Bass AC, et al. Setting a national agenda for surgical disparities research: recommendations from the National Institutes of Health and American College of Surgeons Summit. *JAMA Surg*. 2016;151(6):554-563.

The 2015 National Institutes of Health–American College of Surgeons Summit on Surgical Disparities Research identified the following priorities to guide surgical disparities research: improving patient-clinician communication, fostering engagement and community outreach by using technology, improving care at facilities with a higher proportion of minoritized patients, evaluating the longer-term effect of acute intervention and rehabilitation support, and improving patient-centeredness by identifying expectations for recovery.

Torain MJ, Maragh-Bass AC, Dankwa-Mullen I, et al. Surgical disparities: a comprehensive review and new conceptual framework. *J Am Coll Surg*. 2016;223(2):408-418.

The thematic framework for conceptualizing surgical disparities includes five major themes: provider factors, patient factors, system and access factors, clinical care and quality care factors, and postoperative care and rehabilitation factors.

OUTLINE

Surgical Need Worldwide
Surgical Workforce
Strengthening Surgical Systems
Research and Innovation
  Advocacy in Global Surgery
Creating a Global Surgery Program
  Funding Global Surgery Activities
  Pitfalls of Academic Global Surgical Partnerships
Conclusion

Global health is an area of research and practice that seeks to improve health and achieve health equity worldwide.[1] Within global health, global surgery is a rapidly developing field aiming to improve access to timely, affordable, and quality surgical care across all health systems. It includes the treatment of surgical disease and its equitable provision across health systems *at home and abroad.* It emphasizes horizontal health systems strengthening by addressing various health challenges in surgical care that will enhance health outcomes, particularly in vulnerable populations.[2] Global surgery is inherently multidisciplinary and interprofessional, encompassing all surgical care delivery fields, including surgical subspecialties, obstetrics and gynecology, anesthesia, perioperative care, emergency medicine, rehabilitation, palliative care, nursing, and allied health because good surgical care requires all of this expertise.[3]

This field is a product of centuries of international healthcare and humanitarian initiatives. Historically, surgical care in a global context has long been practiced by faith-based organizations through medical missions. After World War II, there was a proliferation of nongovernmental organizations (NGOs) devoted to the health of people affected by war and its aftermath.[4] Over the past 30 years, academic partnerships involving surgery have increased. *Academic global surgery* is the pursuit of traditional academic goals of clinical care, education, and research, informed by local needs, while leveraging institutional assets to sustainably improve care, modify care delivery models, inform healthcare policy, and measure impact over time. The field has also grown beyond geographical boundaries of humanitarian, faith-based, and war-related surgery with the recognition that disparities in access to timely surgical care exist in every country and every region of the world and that surgical systems need to be strengthened across disparate areas of need.

The more recent inflection point for academic global surgery has been from the ethical dilemma of recognizing the unequal access to quality surgery that exists today *across the globe* and the historical neglect of surgery and surgeons within the global public health sphere. Surgical conditions are estimated to account for 28% of the global burden of disease.[5] In 2015, three key policy milestones occurred. The Lancet Commission on Global Surgery (LCOGS), for the first time, systematically studied and outlined the surgical needs, capacity, workforce, and systems around the world. The World Health Assembly (WHA) passed Resolution 68.15, which included surgery and perioperative care as essential components of universal healthcare. The Chapter on Essential Surgery in the 3rd edition of the Disease Control Priorities book quantified the need for surgical and perioperative services, proposed mechanisms to increase surgical system capacity, and described the economic implications and return on investment associated with surgical care delivery, even in low-resource environments. These key events emphasized the importance of developing regional and national strategies to increase access to surgical care worldwide. Until this point, international health had been dominated, albeit rightly so, for decades by those concerned with infectious diseases, from smallpox to AIDS.[6] However, because most surgical conditions are not transmissible and do not cross international borders, historically they had been omitted as a part of public health needs. They had not been high on the priority list for governmental support and intervention. Furthermore, public health experts previously regarded surgery as a highly complex intervention requiring significant investment in infrastructure and training. However, the increasing global burden of noncommunicable diseases, many of which need surgical management, and key events in 2015 increased interest in surgical system strengthening, especially in the areas of the world with the largest unmet surgical needs and least capacity to deliver surgical care: low- and middle-income countries (LMICs).[7] Global surgery, once considered the neglected stepchild of global public health by Paul Farmer and Jim Kim, has now been adopted officially into the global health family.[5,6,8,9]

In this chapter, we examine the global burden of surgical disease to highlight the unmet need for surgical care, assess the state of the global surgical workforce, and evaluate the role of academic institutions engaging in global surgery activities. Furthermore, we will explore the role of advocacy and funding in making the field of global surgery sustainable and highlight some of the pitfalls that can risk global surgery activities. This chapter applies to surgical systems in low-resource environments worldwide, including within high-income countries and across LMICs. We will conclude by discussing a case study from a low-resource environment in the United States.

SURGICAL NEED WORLDWIDE

Worldwide, the need for surgical care is substantial. Initial expert opinion suggested that 11% of the overall global burden of disease was treatable by surgery, but the work by LCOGS suggests the need could be higher, up to 30%.[8] Around the world, LMICs have to deal with a high burden of infectious diseases and an increasing burden of noncommunicable and surgical diseases, especially road traffic injuries. Injury alone accounts for nearly 5 million deaths per year, or roughly 68% of all global surgical burden. Road traffic injury is the top cause of death of all those aged 5 to 29 years, and people affected by injury often require access to emergency, critical, and operative care services.[10,11]

Access to safe, high-quality, and affordable surgical care is limited worldwide, and there are several challenges for developing surgical systems (Fig. 15.1). The poorest countries, where one-third of the global population resides, conduct only 6% of the 313 million surgeries performed yearly. Some countries report that less than 10% of surgical needs are met (Fig. 15.2).[8,12] National surgical volumes are vital for determining and developing national plans to increase a country's surgical capacity, although they are challenging to determine. Surgical volumes per 100,000 population are calculated based on the reported number of surgeries and population estimates. Surgeries such as hernia and cesarean section often serve as proxy indicators to assess the surgical capacity because a more comprehensive enumeration of all operations performed may not be feasible. Many LMICs lack appropriate mechanisms to estimate the surgical volume regularly, skewing the estimates of met and unmet needs of surgery. Significant heterogeneity exists in the methodologies to assess surgical volumes, and inconsistent reporting hinders comparison between countries. Many surgical procedures that do not get counted are performed in emergency rooms or at the patient's bedside without general or regional anesthesia. The average surgical volume rate in LMICs hovers around 877 surgeries per 100,000 population and does not reach the benchmark set by the LCOGS of 5000 per 100,000 population.[13]

Probability of access is the joint probability of timely care, surgical capacity, safe surgery, and affordability

FIGURE 15.1 Factors affecting access to surgical care.

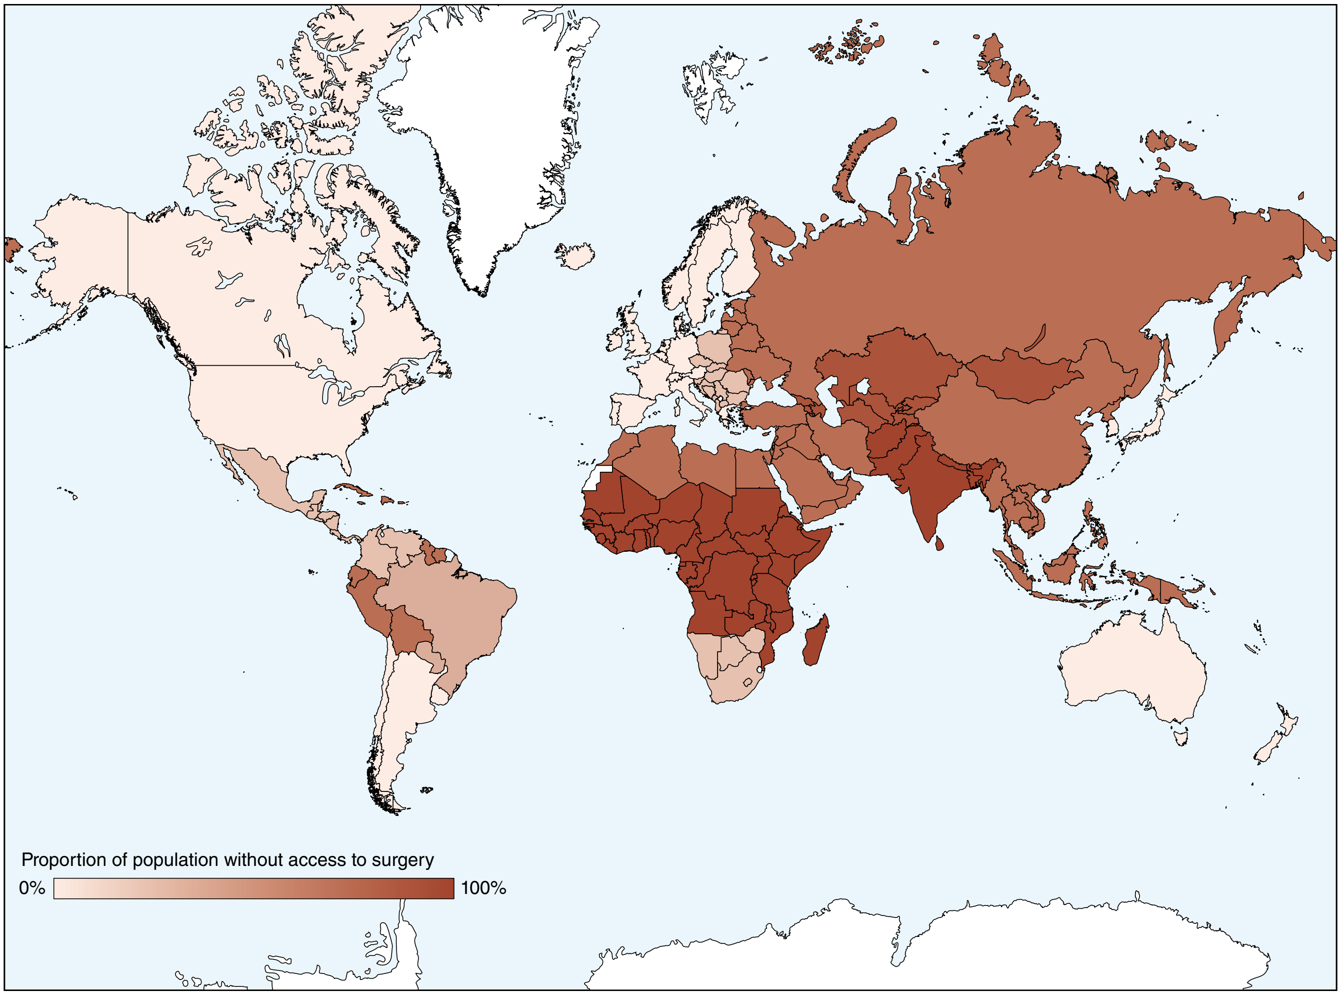
There is also debate around quantity versus quality of care in surgery. The emphasis is on increasing the number of operations and focusing on safe surgery. Some initiatives, such as the Aravind Eye Care System in India, have proven that quality and safe surgery is affordable through the sustainable concept of "high-volume, low-profit," with enhanced hospital recovery and postdischarge follow-up by community health workers.[14] Additionally, the growth of academic partnerships and emphasis on local capacity strengthening can address these historic norms and contribute to higher volumes and better quality of surgical care.

Regardless, surgical care remains one of the world's top creators of new poverty today (Fig. 15.3).[8] Catastrophic health expenditure, which is an out-of-pocket expenditure of over 25% of income, can push families into poverty. The need for emergency surgery can put vulnerable families at risk for catastrophic health expenditures, even with just a one-time payment for surgery. An estimated 44% of the world's population is at risk of financial catastrophe with a single major operative procedure.[8] However, surgical care can be extraordinarily cost-effective compared with a variety of health interventions by a collaboration of health economists, scientists, and clinicians, suggesting that investments in surgical systems are likely to have profound societal benefits (Fig. 15.4).[8] Still, affordable surgical care remains sorely lacking around the world.

Another critical area of need at the global level is benchmarking in surgery. Clinical registries are data repositories with built-in analytic functions that use case-level data to identify potentially preventable deaths and, most importantly, improve the quality of patient care. They can collect integrated data on patient presentation, care, and outcome, from prehospital settings to emergency unit visits and inpatient stays. Then, these data are analyzed to determine whether poor outcomes were potentially preventable. These reports can be fed back to clinical teams for review and targeted education. Such quality improvement (QI) cycles are iterative, directly informing corrective actions over time.[15] DHIS2 is a free and open health information management software with these capabilities, is available for the global public good, and is transforming health information management worldwide. It is used by more than 80 LMICs, and country-level data are owned locally, which takes into account local laws, privacy regulations, and server maintenance capacity. In collaboration with system experts, ministries of health can configure their own information system on top of the generic platform to gather the data relevant to their setting.[16] The World Health Organization (WHO) International Registry for Trauma and Emergency Care (IRTEC) is an example of a system that has been set up to improve trauma care and outcomes and is a part of one of the United Nation's (UN's) Sustainable Development Goals.[17]

SURGICAL WORKFORCE

How can such vast systemic needs be addressed to improve the quality and increase the quantity of surgical care delivered worldwide? The lack of surgeons, obstetricians, and anesthesiologists is



Proportion of population without access to surgery
0%
100%

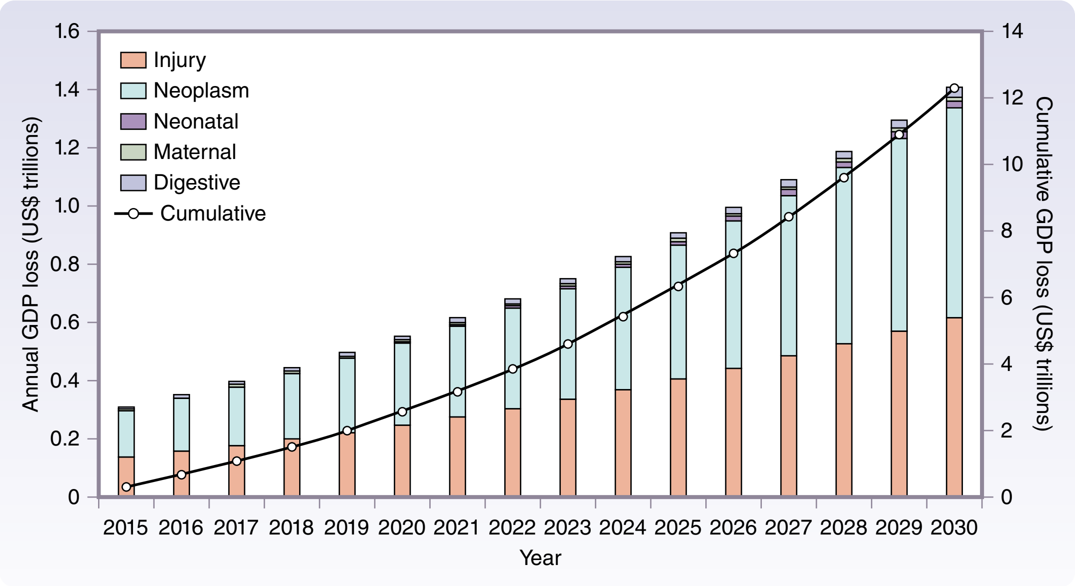

FIGURE 15.3 Annual and cumulative gross domestic product *(GDP)* lost in low-income and middle-income countries from five categories of surgical conditions (2010 US$, purchasing power parity).

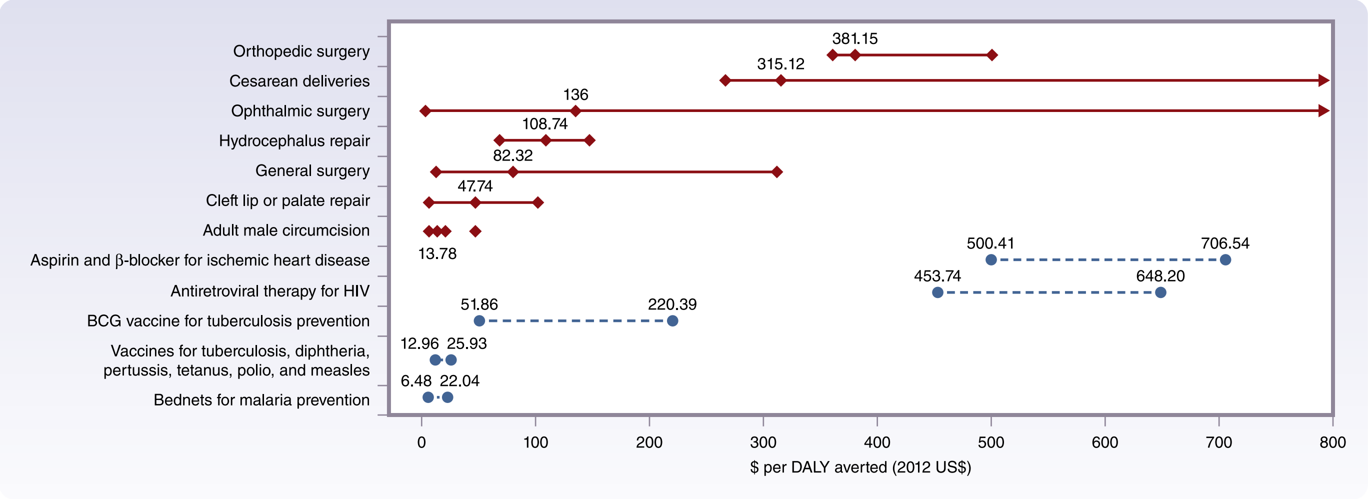

FIGURE 15.4 Cost-effectiveness of surgery in low-income and middle-income countries compared with other public health interventions. *BCG,* Bacille Calmette-Guérin; *DALY,* disability-adjusted life years.

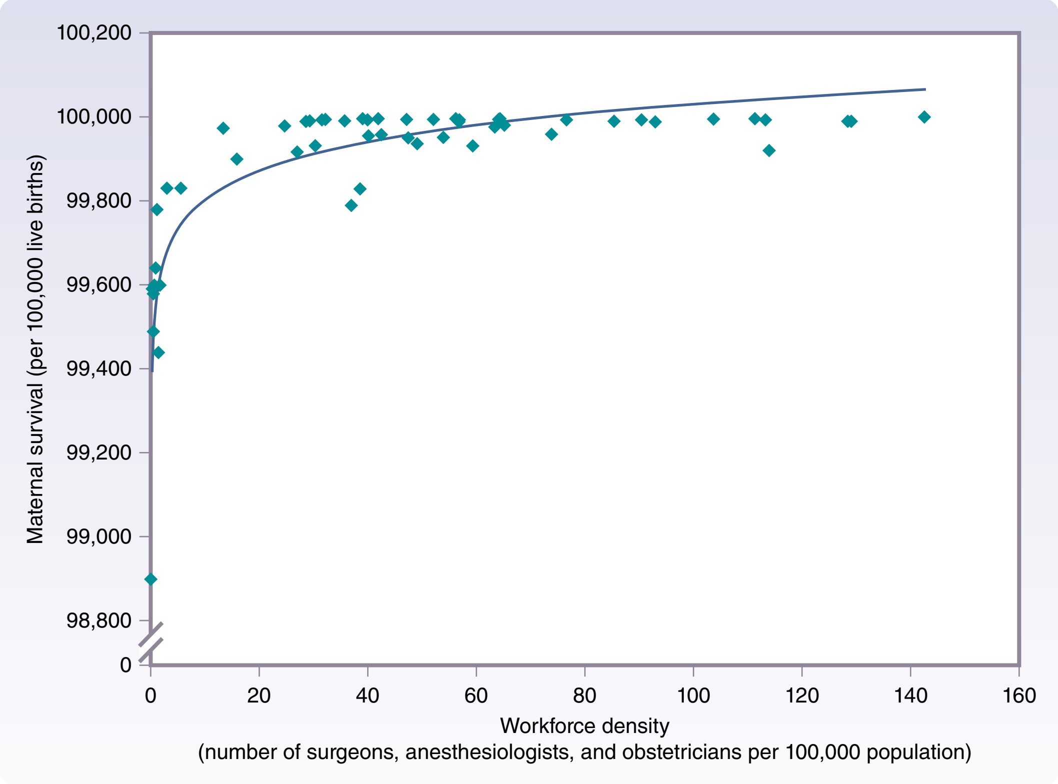

FIGURE 15.5 Specialist surgical workforce density and maternal survival. A surgical workforce density of less than 20 per 100,000 specialist surgeons, anesthesiologists, and obstetricians correlates with lower rates of maternal survival.

an essential cause of the unmet need for surgical care, especially in LMICs. LMICs, which consist of 48% of the global population, have only an estimated 19% of all surgeons. The LCOGS showed that countries with surgeon, anesthetist, and obstetrician (SAO) densities of 20 to 40 SAO per 100,000 population were associated with improved health outcomes (Fig. 15.5).[8] However, based on the WHO Global Surgical Workforce Database, doubling the global surgical workforce would be necessary to meet these SAO density ranges.[18]

To solve the global surgical workforce challenges, many LMIC governments have historically sent physicians abroad to obtain postgraduate training. This strategy was expensive, and the return on investment was never realized because most trainees never returned to their home countries.[19] Many have relied on short-term missions and surgical outreach as stop-gap measures. Additionally, there are negative consequences of short-term foreign medical teams: the local community often perceives intermittent visiting teams as providing higher quality care than the local staff who are delivering care continuously, which inadvertently sabotages trust in the existing health systems.[20,21] As such, strategies focusing on growing local experts have developed through academic partnerships based on mutual interests. Two key examples from the African context are worth discussing.

The collaboration between the College of Surgeons of East, Central and Southern Africa (COSECSA) and the Royal College of Surgeons in Ireland (RCSI) aimed to increase the number of qualified surgeons on the continent of over 1 billion people. COSECSA was established in 1999 as a nonprofit body to provide surgical training across 18 East, Central, and Southern African countries by harnessing and sharing resources and opportunities among the group. It provides internationally recognized surgical qualifications in orthopedics, pediatric orthopedics, ENT, urology, pediatric surgery, neurosurgery, cardiothoracic surgery, plastic surgery, and general surgery.[22] Since 2008, RCSI has collaborated with COSECSA to help rewrite the curricula, develop the first Objective Standardized Clinical Exam, run its examination for membership and fellowship, develop an e-learning platform, and perform other administrative tasks.[23] This collaboration between a professional body from a high-income country and a professional body from LMICs has been vital to training and retaining the surgical workforce within East, Central, and Southern Africa; 85.1% of surgical graduates were retained in the countries they trained in, and 88.3% were retained within the region.[24] Another essential strategy to increase the surgical workforce is the training of females. COSESCA, in collaboration with the American College of Surgeons (ACS), has introduced a scholarship program to support females in surgical residency programs and encourage other females in medical school to consider a career in surgery.[25] Also, the WHO Academy has skill-based courses to teach competencies with certification for the first contact surgical staff (often at the district hospital) for all the 44 essential operations.[26]

Surgery is a team exercise, and surgeons cannot operate in a vacuum; the surgical team includes many health professionals, including anesthesiologists and nurses. Training programs that focus only on surgeons and not the rest of the operating team risk limiting the impact of training surgeons on surgical capacity and care delivery. Academic collaborations that aim to improve workforce training have a better chance of improving patient care while strengthening the healthcare system. For instance, the Rwanda Human Resources for Health Program (HRH Program) was a collaboration between the Government of Rwanda and 22 academic institutions in the United States to train a diverse and competent workforce.[27] As a result of the collaboration, postgraduate training programs for physicians were either started or reinforced in several specialties, including general surgery, obstetrics and gynecology, neurosurgery, orthopedic surgery, and anesthesiology in addition to nursing and nursing subspecialties such as critical care and perioperative care nursing.[27]

Despite the collaborations involved in increasing the surgical workforce mentioned previously, the burden of surgical disease far exceeds the supply of the workforce. In countries with limited surgical workforce, an increase in the number of surgeons, surgical specialists, and anesthesiologists to meet the surgical burden is unlikely to be achieved.[28] Therefore, health systems are identifying other ways to offset the workforce shortage. One method involves mobilizing nonphysician clinicians to perform surgical and anesthetic tasks.[29] This approach, called *surgical task-sharing*, is delegating tasks traditionally performed by surgeons and anesthesiologists to less specialized healthcare workers.[30] As a result, nonphysician anesthetists may deliver anesthesia, and nonphysician clinicians may perform essential surgery under the oversight of physician specialists.[31] With appropriate levels of oversight, surgical outcomes can be comparable between specialists and nonphysician clinicians.[32] However, there is still debate in the literature regarding the safety and quality of task-sharing and the attendant implications for traditional training.[33]

Based on the enormous unmet need, there must be a balance between meeting the urgent demand for surgical services and creating sustainable improvements in local healthcare infrastructure. Both are challenging. A combination is necessary, yet the limited financial resources often lead charitable organizations to fight against each other for financial support to have a substantial impact. Furthermore, no established guidelines exist to assist stakeholders with the ethical dilemmas encountered in global surgical partnerships. Additionally, there is a lack of input in the literature on this topic from LMIC experts.[34] These issues must be considered by collaborations engaging in global surgery partnerships. Ultimately, there is a need for a self-sustaining model to train and retain a high-quality surgical workforce worldwide to achieve surgical system strengthening in communities where the need is the greatest.

STRENGTHENING SURGICAL SYSTEMS

Strengthening surgical systems requires understanding the resources available, the existing healthcare delivery models, the governance structure, and the governmental support in the region. In addition, the entire continuum of care, from health promotion, prevention, and treatment to rehabilitation and palliative care services, must be considered to deliver high-quality surgical care. The surgical ecosystem—the people, infrastructure, and processes involved in providing all surgical and subdisciplines, anesthesia, nursing, and critical care services—is an essential ingredient of health systems.[35]

The critical first step is understanding this ecosystem and existing infrastructure in resource-limited settings, which may require a needs assessment or asset mapping. Depending on the results, there must be engagement in building or strengthening surgical infrastructure, including hospitals, operating rooms, and intensive care units, and acquiring adequate surgical equipment to allow surgical procedures to be done.[10]

Second, collaboration with local healthcare systems and organizations is essential. This must include explicit plans for enhancing the capacity of the local staff and system to deliver surgical care independently and sustainably based on local needs. This can involve knowledge transfer, surgical skills training, and mentorship programs.[36–39] This focus on local staff capacity must include collaboration between surgical specialties and other medical disciplines to provide comprehensive and effective patient care. Surgical care requires effective systems with experts across disciplines and professions.

For example, collaborating with anesthesiologists is crucial to achieving successful surgical outcomes and improving healthcare access. A recent publication evaluating the anesthesia-related capacity of 22 LMIC facilities from Asia and Africa determined that over a third did not have access to oxygen or anesthesia machines.[8,40] Focusing on training surgeons alone would be ineffective without anesthesia capacity. Furthermore, as we have all learned through the COVID-19 pandemic, critical care specialists are essential for health systems. They are also essential for delivering high-quality perioperative care after complex injuries and operations.

Strengthening capacity for surgical care has significant knock-on effects on other disciplines, such as obstetric and gynecologic specialists. Maternal and reproductive health conditions account for a substantial aspect of the global burden of surgical diseases.[41] Many surgical interventions are related to obstetric emergencies, such as cesarean sections and repair of obstetric fistulas. The same systems needed for postpartum hemorrhage management, such as blood banks and critical care services, are essential infrastructure for general surgical care. It is vital to recognize these synergies early in any collaboration.

Child health is critically important and undervalued based on the world's demographics. Many studies have underlined the dramatic shortage of pediatric surgeons and healthcare assistants in low-resource environments, particularly in Africa.[42,43] Increasing the pediatric surgical workforce is essential, though embarking on training general surgeons in basic pediatric surgery may help bridge the gap. Identifying centers that can deliver quality pediatric surgical care, particularly in children with congenital anomalies, is imperative.[44] Collaboration with pediatric surgeons ensures comprehensive and high-quality surgical care. The Global Initiative for Children's Surgery is an association focusing on capacity strengthening in pediatric surgery.[45]

Worldwide, the burden of cancer is only increasing.[46–48] Surgery is essential to cancer care, and pathologists and radiologists are critical partners in delivering high-quality cancer care. Collaboration with surgical pathologists helps in the accurate diagnosis and staging of diseases that ultimately impact treatment and prognosis and in determining the cause of death.[49] Similarly, radiologists are vital for accurate preoperative planning and postoperative assessment. Imaging helps diagnose conditions, plan surgical approaches, and monitor postoperative outcomes.[50] The COVID-19 pandemic has empowered various teams to think creatively about collaborating on cancer care.[51,52] Again, surgeons have a prominent and essential role in these multidisciplinary partnerships.

Nurses and allied health professionals are the unsung heroes of every health system, and surgical systems are no different.[53] Collaboration with nursing staff, pharmacists, physiotherapists, and other allied health professionals ensures comprehensive preoperative and postoperative care and rehabilitation.[53–55] Surgical collaborations should not only be limited to training local surgeons but include a broader view that includes such staff who are critical to delivering high-quality surgical care. Lastly, healthcare systems cannot run without administrators and health economists. They are crucial for ensuring sustainable and cost-effective delivery of surgical services and successful collaboration with NGOs, international organizations, and humanitarian agencies that can help mobilize resources, provide training, and facilitate the implementation of surgical programs in low-resource environments.[35,56]

Third, it is essential to understand local governance, priorities, and support by the government. For example, many countries have developed national surgical, obstetric, and anesthesia plans to reach an internal consensus on their needs, priorities, and goals.[57–61] A key area of focus for many settings is providing emergency surgical care. Ensuring timely access and intervention to emergency surgical services such as trauma care, obstetric emergencies, and other urgent surgical conditions can significantly impact patient outcomes.[62] The delivery of emergency surgical care can improve equity, particularly for marginalized and underserved populations, including remote rural communities and vulnerable groups. As such, this is often a critical initial area of focus for LMICs. Delivering emergency surgical care may involve developing innovative healthcare delivery models that maximize the impact of surgical services by integrating them into existing primary care networks and health systems.[63]

Trauma and emergency care systems are great examples of the comprehensive model that surgical systems need globally.[62,64] The burden of trauma is significant globally, particularly in musculoskeletal, traumatic brain, and spine injuries.[65] Collaboration between orthopedic surgeons and neurosurgeons is essential. Although models of international collaboration have been demonstrated to work in other specialties, orthopedic surgery and neurosurgery still lag and require scaling up within the global surgery space.[66] There are ongoing efforts by neurosurgical societies and philanthropic foundations to address the deficit of neurosurgeons in LMICs, especially in Africa and Southeast Asia.[67] Key tools such as the WHO's materials for strengthening emergency care systems and the essential elements for trauma systems developed by the ACS Committee on Trauma may be valuable examples to systematically improve surgical systems.[62]

Lastly, to determine the effectiveness of global surgical efforts, we must collect data on surgical needs, outcomes, and challenges to inform evidence-based decision-making health policy and to advocate for integrating surgical care into national and international health policies as a part of universal health coverage.[68] Research helps identify effective strategies for improving global surgical care, emphasizing patient safety and QI.[68,69] These steps are challenging yet essential for any program to strengthen surgical systems in resource-limited settings.

RESEARCH AND INNOVATION

Surgical systems are complex, and there are no rapid or easy ways to increase the volume and quality of surgical care available in low-resource environments worldwide. Surgical research and innovation are essential for improving surgical systems regardless of resource environment.[70] Surgical research can identify regions with unmet needs and determine the resources required to meet these needs.[71] Similarly, innovative strategies and interventions can help address programmatic, process, and product needs and improve the delivery of high-quality surgical care.[70]

To improve surgical care delivery, we need to understand the needs, constraints, and resources within a particular environment and develop context-specific interventions that can be implemented effectively to improve the quantity and quality of care delivered. This applies to surgical care regardless of country or degree of resource availability. Three areas of academic expertise in surgery are essential to improving surgical care delivery, especially in environments with limited resources and high unmet needs: health services research, QI, and implementation science.

Health services research is a multidisciplinary field that studies the cost, quality, delivery, and outcomes of surgical care. A great example is a series of papers in *The Lancet* 2015 issue on core indicators to assess surgical systems.[8] These *Lancet indicators,* as they have become known, have now been applied in various contexts to study the capacity of a country's ability to deliver surgical care. The Latin American Indicator Research Collaboratory (LAIRC) is based at Rutgers University in New Jersey and "serves as a foundation for applying core surgical world development indicator data collection, analysis, and interpretation in a systems-based surgical education and training research model."[72] LAIRC has since produced assessments led by surgical and perioperative experts from health systems across numerous countries in the Latin American region.

The National Institute of Health Research Global Health Research Unit on Global Surgery is another outstanding example of worldwide research into surgical service delivery. The Birmingham and Edinburgh universities in the United Kingdom founded this collaboration. Through collaborative research, they created hubs in Ghana, Nigeria, India, Rwanda, Mexico, South Africa, and Benin to improve surgical outcomes worldwide. This collaboration has conducted numerous multicountry randomized controlled trials with tens of thousands of patients to study the delivery of surgical care across resource settings, such as the recent ChEETAh trial, which is a pragmatic, cluster randomized intervention trial in seven countries. The trial enrolled over 13,000 patients and found that surgical site infection rate was substantially lower with routine sterile glove and instrument change at the time of abdominal wound closure (18.9% vs. 16%, adjusted risk ratio of 0.87, 95% CI 0.79–0.95; $p = 0.0032$).[73] The results of this collaboration have contributed to changes in health policy within the country hubs.

The African Perioperative Research Group, a leading network that develops, supports, and coordinates large-scale clinical studies and trials in the African setting to improve the health outcomes of patients receiving perioperative care. They also conducted the African Surgical Outcomes Study, which was the first international African, multicenter, cluster randomized trial conducted in 2016 across 247 hospitals in 25 African countries, recruiting nearly 11,500 patients and including over 1000 African clinician investigators.[74] This seminal study found that 57% of operations across this continent were urgent or emergent, 33% of operations were cesarean sections, and postoperative complications occurred in over 18% of patients, with infection being the most common complication. Subsequently, the group has studied COVID-19, critical illness, and pediatric surgical care on the continent.

QI builds on health services research to change the quality of surgical care. This is a critical need in low-resource environments, which must maximize the ability of the surgical system to deliver the best quality of care and prevent complications and death.[75] A classic example of QI work is development and implementation of the Surgical Safety Checklist and its value in low-resource environments.[76] However, developing such programs requires training in QI principles, at the very least, which is not readily available across low-resource environments, even though maximizing quality of care despite limited resources is essential in such settings. Furthermore, implementing interventions to improve systems can be challenging. This has led to increasing interest in implementation science, which studies how to implement interventions effectively.[77,78] A great example is the African Surgical Unit-based Safety Programme, which adapted and co-developed a complex intervention and related tools designed for high-income country settings—a multimodal surgical site infection prevention strategy—and implemented it across multiple major hospitals in East and Southern Africa. The Programme resulted in a nearly 60% reduction in surgical site infection risk across all sites due to the intervention.[78]

There are numerous challenges to conducting such work in low-resource environments. First, there are few local experts available to deliver care, let alone conduct research. There is a serious lack of local experts with knowledge about these academic areas. The need for research capacity and training is a critical gap without which low-resource environments simply cannot grow and are obliged to depend on external experts who may know a particular subject but have no understanding of the subject in that low-resource environment context. Formal training in such work is lacking around the world. A recent paper in *BMJ Global Health* noted the lack of graduate education in global health, including research training. As of 2020, there were only two master's level programs in all of Asia focused on global health, one on the continent of Africa, which has a population of over 1 billion people, and none whatsoever on the continent of South America (Fig. 15.6).[79] Second, the publish-or-perish mentality in academic environments encourages extractive research without adequate involvement or recognition of local investigators and further disempowers local staff.[80] Lastly, access to funding, especially for global surgical research, still largely relies on high-resource environments and the politics and priorities of those settings, which affects what is studied and valued.[81–83]

The availability of surgical services also faces significant challenges in low-resource environments due to the scarcity of surgical supplies and equipment. According to the WHO, approximately 95% of medical equipment in LMICs is imported, with about 80% of this funding from international donors or foreign governments.[84] Surgical care and innovation go hand in hand.[70] Innovation is defined as new and better ways of solving problems and improving healthcare delivery in a scalable manner. It can include innovations in programs, policies, systems, processes, services, technologies, and products.[85,86] Surgical systems can benefit greatly from innovations in these areas, especially since surgical and perioperative innovation can strengthen broader health system capacity.

Innovation in surgery can range across a wide and interrelated spectrum of program, product, and process innovation. Program innovations can start with a new product, such as the development of the cardiopulmonary bypass machine in 1951, which has led to the development of cardiac surgery and entire professions, such as the cardiac perfusionist.[87] Process innovations such as the Surgical Safety Checklist discussed previously have drastically improved care by standardizing routine processes.[87] More recently, disruptive innovations in low-resource environments have been great examples of leap-frogging, which is the concept of using a technology, model, or process to accelerate development by skipping over development stages that had previously been unavoidable. Examples include communication tools such as WhatsApp to triage fracture or burn care in South Africa. WhatsApp was used in 2017 and 2018 even before the COVID-19 pandemic forced health systems to use unexpected and radical ways to manage capacity demands.[88,89] Great examples of product innovations that can be seen as frugal or low-cost innovation include the low-cost lenses developed by the Aravind Eye Care System, which have revolutionized access to affordable vision care worldwide.[14] Product innovations are also considered "reverse innovations" based on applicability to rich countries, including the "Bogota bag" for damage control laparotomy, which has since spawned a multibillion dollar industry in negative pressure vacuum therapy and is now used routinely in surgical care worldwide.[90]

There is an especially great need for innovation in surgery in low-resource environments because of the massive unmet needs and equally staggering resource constraints. The opportunities to innovate are more significant than ever.[8,91] Whether programmatic in increasing surgical workforce capacity, skills, or quality (including concepts such as task-sharing) or developing processes to deliver standardized care or creating new tools and techniques for surgery, there are substantial opportunities for innovation in surgery. There are, however, significant challenges to innovating in low-resource environments. For example, who is responsible for medical education and training can vary across settings and can lead to controversy because producing and certifying a cadre of professionals or surgeons with specialized skills does not mean that health systems will necessarily have mechanisms to hire them on to deliver care, especially in settings that have specific systems in place (US Indian Health Service) or that have a meagerly

funded public system to care for the majority of the population (most LMICs). Furthermore, a lack of regulatory infrastructure and intellectual property laws, as well as physical resources for product development such as prototyping facilities, can limit the capacity of experts who understand the context and surgical needs from ever being able to innovate and scale a product that fits the local market (Table 15.1).

Regardless, rigorous research and innovation are essential to address the enormous need for surgical care. Although surgical systems may be complex, and no silver bullets exist to increase the volume and quality of surgical care rapidly, there is momentum to build systems in low-resource environments that can evaluate themselves and innovate to meet local needs while delivering good quality care.

Advocacy in Global Surgery

Momentum for change and funding comes from advocacy. The year 2015 was a watershed year for global surgery. WHA Resolution 68.15 on strengthening emergency and essential surgical care and anesthesia as a component of universal health coverage, the LCOGS, and the Disease Control Priorities (DCP3) helped move surgery to be accepted as a part of public health.[8,9] The premise that surgery and anesthesia services are embedded within overall health systems and primary healthcare and that surgical services require a coordinated, strategic, and integrated care approach to deliver effective care became evident. However, in low-resource environments, due to the substantial human resource shortage across every discipline and health profession, the delivery of surgical services cannot be focused on any single health worker cadre, specialty, condition, or setting. Single disease–based or self-contained curative care models that can risk undermining the ability of health systems to provide universal and financially sustainable care also cannot be the standard. Thus, the focus has been on broadly integrating surgical and perioperative care into health systems.

Political will and support of the Ministries of Health of all countries are created through WHA resolutions. Since the WHA68.15 (2015), two more resolutions have been passed relating to surgery. The WHA72.16 (2019), on emergency care systems for universal health coverage, calls for national policies and plans for sustainable funding and effective governance, including coordinating and regulating public and private sector actors to deliver surgical and operative care services. In 2023, the Emergency, Critical, and Operative Care Resolution reinforced the previous ones. All advocated for capacity building through pre- and in-service skill-based training for relevant frontline healthcare workers providing surgical service, such as via the WHO Academy. All also reinforced the key need for systematically collecting and evaluating patient data to improve the quality of surgical care and have urged the use of clinical registries and audits for this purpose.

TABLE 15.1 Examples of Innovation in Global Surgery

Innovation type	Program	Safe Surgery 2020; The RCSI-COSECSA Collaboration Program; The Human Resources for Health Program in Rwanda	Requires partnerships between major academic medical centers, universities, public and private organizations; can be highly complex to organize and coordinate	Multidisciplinary, interprofessional, large-scale population-level impact, capacity building through training in technical skills and processes, transformative in nature	Requires massive financial investments, substantial time commitment, engagement across disparate and sometimes nonaligned stakeholders with varying priorities
	Process	WHO Surgical Safety Checklist; WhatsApp-based triage for burn or fracture care	Needs engagement between departments and institutions across an institution or a region with multiple institutions	Multidisciplinary, interprofessional, hospital-level impact across all surgical conditions	Requires buy-in and culture change across disciplines and professions, which takes time and political commitment at the institution level
	Product	Low-cost cataract lenses; "Bogota bag" and other negative pressure wound therapy products	Tends to function at a small scale with partnerships between individuals across institutions and organizations including industry and/or government	Addresses a specific need/solves a clear problem, has individual-level impact, potential for financial returns for investors	Needs product development and testing expertise, needs local manufacturing capability, complicated regulatory infrastructure for safety assessments and approval may not exist to bring product to market

COSECSA, College of Surgeons of East, Central and Southern Africa; *RCSI,* Royal College of Surgeons in Ireland.

However, the global surgery community still needs a formulated and coordinated strategy to become a movement like maternal health, with massive support from major global funders. First, we will need a benchmarking global report to determine the current status of national surgical healthcare policies across countries, including policy frameworks, regulations, and financing mechanisms. Second, using the status report, ministries of health should examine the existing surgical infrastructure, workforce capacity, and technology integration in healthcare systems so that they co-own the state of their health systems. Third, a package of surgical services, tools, and policies that fit each country's purpose and context should be developed that would allow intercountry comparisons. For example, a tool such as the Surgical Safety Checklist prompts global standards and can be used for advocacy worldwide. Implementing such tools and registries will be challenging, particularly in low-resource environments, but the involvement of key stakeholders in the global surgical community early in the process can help ensure ownership and advocacy.

There are disparate stakeholders engaged in the global surgery community. Government policymakers and health ministries, international organizations and NGOs working on healthcare and surgery, healthcare professionals and surgical practitioners, academicians and researchers in healthcare policy and surgery, patient advocacy groups, and civil society organizations focusing on surgical healthcare access and equity are all vested in the delivery of high-quality and affordable surgical care. Only when these disparate stakeholders work together and develop a feasible global action plan to address surgical access across LMICs will funders be willing to see surgery as a significant global health problem that merits investment.

Annually over $4 billion are available for HIV, malaria, and tuberculosis (TB) combined, whereas only negligible funds are available for surgically avertable deaths, though the latter are much greater in burden. Injury alone is estimated to account for 68% of surgical conditions and accounts for nearly double the burden of HIV, malaria, and TB combined (Fig. 15.7). Unfortunately, while academic global surgeons focus on measuring and calibrating the magnitude of the problem, major global funders seek actionable implementation plans from stakeholders in the global surgical community. The Global Surgery Foundation is mandated to create the Global Fund for Surgery to pool resources, similar to the Global Fund for Tuberculosis and the Global Alliance for Vaccines and Immunization (GAVI).[92] However, the global surgery community has not yet been organized enough to benefit from such innovative financing to have impact at scale.

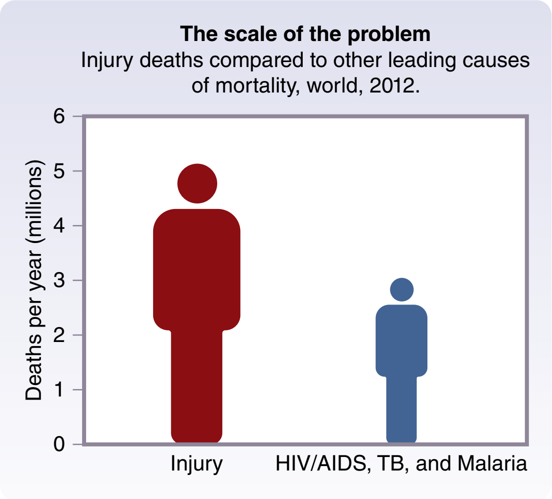

FIGURE 15.7 Injury alone dwarfs the big three injury accounts for only 68% of global burden of all surgical diseases, which means that including surgical conditions would raise this disparity by an additional 30%. *TB,* Tuberculosis.

The way forward for global surgery is stronger two-way partnerships between surgeons in academic university hospitals and the surgical workforce delivering care in the community. Surgeons must go beyond the technical aspects of surgical practice to advocate for affordable and equitable surgical care for everyone everywhere without compromising safety. They must work together with other key stakeholders involved in surgical systems to map out the mechanisms needed to exponentially ramp up surgical care delivery.

CREATING A GLOBAL SURGERY PROGRAM

There is great potential for surgeons and their institutions worldwide to help address the unmet need for surgical care by collaborating to strengthen healthcare workforce capacity development, research, and innovation. Divisions, programs, centers, and institutes have formed across several universities to strengthen surgical systems worldwide.

An outstanding example is the Division of Global Surgery at the University of Cape Town.[93] It has four clusters: Education, Research, Implementation, and Advocacy. The Education cluster runs initiatives such as short courses, master's degrees, and leadership programs in global surgery, including PhD-level training. The Research cluster has a clear framework for global surgical research, including specific objectives and goals to contribute to strengthening surgical systems in the African setting and worldwide through building locally relevant evidence. The Division of Global Surgery is also home to the African Perioperative Research Group, as noted previously (see the section "Research and Innovation"). The Implementation cluster has projects to support clinical service delivery across various staff in community and district hospitals. It aims to standardize and implement the principles of early recovery after surgery. The Advocacy cluster seeks to address social determinants of health that affect the quality of surgical care available to vulnerable and underserved populations through public and community engagement, diplomacy, and being a voice for these populations.

Several unique programs in the United States are excellent examples of institutional commitment to this evolving field of academic global surgery. The Center for Global Surgery at the University of Utah is the oldest such center in the United States. It has four pillars much like the University of Cape Town, including Programs, Education, Research/Innovation, and Advocacy.[94] The Center has long-standing partnerships in 7 countries with 15 grant- or philanthropy-funded programs in general surgery, laparoscopic surgery, trauma, surgical oncology, colorectal surgery, transplant surgery, vascular surgery, urology and plastics, and reconstructive surgery. The founders led advocacy at the UN for the passage of WHA Resolution 68.15 and contributed to the LCOGS and helped launch several major societies, such as Consortium of Universities for Global Health (CUGH); The Global Alliance for Surgical, Obstetrics, Trauma, and Anesthesia Care (G4 Alliance); and The Association of Academic Global Surgery (AAGS). The Center has established education pathways for every level of trainee to learn about the field, such as the inaugural Global Surgery fellowship at the ACS, and recently led the development of universal competencies in academic global surgery (Table 15.2).[95] The Center has research expertise in data science, QI, and qualitative and quantitative analysis, and it leads a multidisciplinary and interprofessional global health innovation track in the Masters of Science in Clinical Investigation offered by the Utah Clinical and Translational Institute. Center faculty have multiple grants from foundations and research entities, including the National Institutes of Health (NIH), to conduct global surgical research. The Center also funds seed grants from philanthropic sources to support early collaborations across specialties and departments.

Other great examples include University of California Los Angeles Program for the Advancement of Surgical Equity (PASE) and University of California San Francisco (UCSF) Center for Health Equity in Surgery and Anesthesia (CHESA).[96,97] PASE also includes local injury and violence prevention activities that address social determinants of health domestically. CHESA includes a partnership with the UCSF Health, Equity, Action, and Leadership (HEAL) Initiative, which offers board-eligible/board-certified clinicians across professions to work in health facilities serving the Navajo Nation, in addition to communities in Uganda, tying together the concept that principles in this field apply in domestic and rural low-resource environments as well as across the globe. PASE and CHESA use the same academic pillars of education, research, advocacy, and service as the programs in Utah and Cape Town.

In setting up such programs, surgeons need institutional support, including administrative, programmatic, and research funding in the short and long term; networks of philanthropists who share the mission; the ability to acquire and manage large-scale extramural funding; and faculty and trainees interested in engaging in collaborations. These highlighted programs are all supported by a variety of institutional sources: university-level departments of surgery alone (PASE) or in partnership with other departments, such as Department of Anesthesia (UCSF) and/or Department of Obstetrics and Gynecology (Utah), or by university-level global health institutes (UCSF) or faculty of health sciences (University of Cape Town [UCT]). These programs all have established cross-institutional partnerships that require memoranda of understanding (MOUs), which outline the partnership's goals, anticipated milestones, resources contributed by each partner, and expectations of outputs over a specified timeline. These MOUs act as cooperative agreements between each institution's legal entities, ensure that ownership and accountability are specified at the outset of any partnership, and are fundamental steps to setting up a global surgery program. Because education is a fundamental aspect of global surgery programs, creating short courses or granting formal degrees is essential. The recently published consensus-based framework of competencies in academic global surgery and perioperative care may be a useful starting point for creating educational content in this field.[93]

The metrics of success to measure these programs have not been established. However, the focus of output should be on sustainability or long-term capacity building in surgical systems, not simply the number of staff trained or operations done. The goals of such programs are to strengthen surgical systems and improve access to surgical services for patients worldwide, and, as such, success has to be measured in the long run.

Funding Global Surgery Activities

Funding for global surgery activities can be approached from two perspectives. One is the lens of surgical clinical care delivery in a low-resource environment, which is almost always the responsibility of the local Ministry of Health or a governmental agency, with or without the assistance of foreign governments, aid agencies, or other partners. The other perspective is funding for academic partnerships between the institutions of high-income countries and those in LMICs engaged in global surgical education and research initiatives. Functioning surgical ecosystems are needed to counter the rising surgical demand in LMICs due to the epidemiologic transition from communicable to noncommunicable diseases.

Yet, the current financial support for surgical care in LMICs is limited. Inadequate financial investment in surgical healthcare delivery is a principal driver of health system shortfall, even

TABLE 15.2 Consensus-Based Universal Competencies for Academic Global Surgery and Perioperative Care

	COMPETENCY		OBJECTIVE
1	Global Burden of Surgical and Perioperative Conditions and Injuries	a	To understand general public health concepts including epidemiology, measures of morbidity and mortality, and multiple determinants of health in relation to the global burden of surgical disease (GBSD) within and across various geographical areas
		b	To gain familiarity with major public health efforts to reduce the GBSD (e.g., Global Surgery Indicators, Sustainable Development Goals in relation to surgery) on a macro-specific and regional/ethnic-specific level and the challenges these initiatives face
		c	To develop a fundamental understanding of analyzing, interpreting, and auditing public health data on surgical and perioperative morbidity and mortality across different settings (e.g., WHO IRTEC, GLOBOCAN, local surveillance data)
2	Globalization of Health, Health Systems, and National Surgery Plans	a	To identify how global trends in healthcare practice, commerce and culture, multinational agreements, and multinational organizations contribute to the quality and availability of surgical care
		b	To explain how travel, trade, natural disasters, and armed conflict contribute to surgical and perioperative problems (e.g., tobacco products and cancer epidemiology, trauma patterns and refugee status secondary to war)
		c	To define core principles of healthcare economics in surgical services delivery and analyze various models of financing healthcare and national health plans
		d	To define and introduce the concept of National Surgical, Obstetric and Anesthesia Plans (NSOAPs)
		e	To understand surgical systems strengthening as an indicator of preparedness for pandemics and natural disasters
		f	To identify the roles of major social, civic, and political entities (i.e., district-level health systems, national health systems, ministries of health and sociopolitical influences such as capitalism) impacting the development of local and regional surgical practices and inequities
3	The Impact of Social and Environmental Determinants of Health and Surgical Care	a	To define cultural influences and historical contexts and to understand how these factors impact perceptions, stigma, and belief systems surrounding surgical care
		b	To list the major social, political economic, and environmental determinants of health leading to regional (local and macro level) disparities in surgical access and outcomes
		c	To understand how resource limitations (including limitations in workforce, infrastructure, medical equipment, etc.) impact practice patterns in various settings
4	Strengthening Surgical Systems Capacity	a	To explore and understand the surgical ecosystem inclusive of anesthesia, nursing, allied health, and all hospital systems related to procurement, supply chain, etc., and to be able to identify the cause of major barriers to creating or sustaining an efficient and effective system
		b	To demonstrate the impact of a strong surgical system on the entire healthcare system of a community and to identify the successful components of creating and maintaining the surgical ecosystem (including all care providers, referral systems, and decision-making parties involved in surgical care access locally)
		c	To establish the importance of monitoring and evaluation (M&E) as a key component of surgical services and to understand the components of implementing M&E, which should be defined and led by local, national, or academic institution leadership
		d	To demonstrate the planning, implementing, and evaluating of evidence-based QI programs, informed and led by local clinical QI teams, that deliver improved and sustainable surgical outcomes
5	Characteristics of Effective Collaborations and Partnerships	a	To identify how successful bidirectional or mutually beneficial engagements function in the context of global operating systems, with inclusion of concepts such as sovereign obligation, transparency, health inequities, global health diplomacy, and cultural humility
		b	To understand the practical aspects of identifying and entering bidirectional/mutually beneficial engagements for improving surgical care (e.g., initiating early communication, MOUs), identifying signs of a failing partnership, and problem-solving when partnership agreements are not upheld
		c	To identify challenges associated with surgical advocacy and implementation of change with an awareness of cultural context, the sustainability of donor-driven partnerships, and imbalances of power in a region outside of one's own background
6	Ethics and Professionalism in Global Surgery	a	To understand basic ethical principles (beneficence, nonmaleficence, justice, respect for persons, etc.) and define the common ethical variations and challenges unique to delivery of surgical care in diverse cultural/political/economic settings, with an emphasis on practicing within one's skill and experience level
		b	To demonstrate understanding of local, national, and international codes of ethics relevant to the surgical and perioperative work environments, including the International Ethical Guidelines for Biomedical Research Involving Human Subjects, and how they influence the practical application of surgical ethical principles in patient care and research

Continued

TABLE 15.2 **Consensus-Based Universal Competencies for Academic Global Surgery and Perioperative Care—cont'd**

	COMPETENCY		OBJECTIVE
		c	To understand the ethical considerations related to neocolonialism and actionable steps that can be taken to achieve the decolonization of surgical and perioperative care, as well as to understand the impact of surgical missions on local communities
7	Health Equity, Social Justice, and the Right to Essential Surgical Care	a	To understand relevant international and regional organizations in linking health and human rights and the Universal Declaration of Human Rights, and how international and national organizations are networking and advocating for local solutions to the challenges in delivering quality health to all based on human rights
		b	To define the universal right to access timely, safe, and affordable essential surgery, and demonstrate a basic understanding of the relationship between health, human rights, and global inequities
		c	To describe and demonstrate how to implement strategies to engage underserved populations in making decisions that affect their health and well-being
8	Leadership	a	To describe the challenges inherent to being an effective leader in groups with members from various backgrounds and in different contexts (e.g., academic, humanitarian, clinical, and research) within global surgery, with an emphasis on developing local, regional, and national leaders in countries where they are most needed
		b	To demonstrate the characteristics of an effective mentor to junior members of the surgical and perioperative team and peers within the field of global surgery and to understand how to nurture leadership potential, with an emphasis on fostering mentorship at the local and regional level
9	Research Equity and Publication	a	To understand principles of research ethics regarding conduct of surgical and perioperative research, including the concept of informed consent, and to identify challenges to performing collaborative surgical research with mutual benefit to all parties involved
		b	To describe how to determine equitable contribution and credit and to promote research capacity strengthening by training and mentoring
		c	To participate in a research project that embodies the values of ethics and equity and that demonstrates locally defined and prioritized advancement in the field in global surgery
		d	To develop skills in utilizing research findings for advocacy in global surgery and translating research into clinical practice and policy

IRTEC, International Registry for Trauma and Emergency Care; *MOU,* memoranda of understanding; *QI,* quality improvement.

though failure to invest appropriately in surgical ecosystems leads to substantial health and economic loss.[98] Unfortunately, resource mobilization for surgery in LMICs is grossly deficient due to the double jeopardy of an overall constrained fiscal space for health and poor political prioritization of surgery. In most LMICs, national- or subnational-level budgetary allocations or actual expenditures for surgery do not exist. The LCOGS recommended that LMICs develop National Surgical, Obstetric, and Anesthesia Plans (NSOAPs) structured into five domains: service delivery, infrastructure, workforce, information management, and financing.[99] Despite the strategic efforts taken by numerous LMICs to develop NSOAPs to address surgical needs at a population level, financing these policies remains a challenge. Relying on current government models and systems of healthcare funding for the implementation of an NSOAP may not result in implementation. Because of concerns with reliance on donor funding or foreign aid to finance critical health interventions, external sources should play only a catalytic role, with the primary financing for health mobilized from domestic sources. It is crucial to find sources of in-country funding outside regular healthcare budgeting, but this remains a challenge in impoverished countries.

One domestic source of funding can include creating or expanding health insurance schemes. In Rwanda, health insurance has improved access to all healthcare.[100] The involvement of the private sector or the development of private-public partnerships is another avenue to generate healthcare system funding. The private sector's participation in healthcare encompasses service delivery, research and development, manufacturing and supply, wholesale and retail distribution of new health technologies, medicines, vaccines, diagnostics, health, insurance, and medical education.[101] The government can also generate funds for the healthcare sector by increasing taxation, particularly corporation taxes, but the political will is challenging, and the tax base of a relatively small number of wealthy corporations may be a substantial limitation.

NGO funding for sustainable capacity building in surgical care has been limited. From 2008 to 2013, charitable organizations contributed approximately $27 billion to global health initiatives, with roughly only 12% allocated to surgical services, and a substantial portion of these philanthropic contributions predominantly did not fully align with the needs of global surgical care.[35] Evaluating the sources providing capital and humanitarian aid is complex due to the diversity of thousands of divergent NGOs and other entities.[102] Thus far, evidence demonstrates that specialized surgical centers seem to provide far more cost-effective care than short-term surgical missions, except when there is no other possible service.[103]

There are also efforts to monitor the allocation of funds dedicated to surgical care to quantify existing investments and financial deficit gaps, which can foster transparency within global health financing.[38] However, numerous NGOs are actively engaged in the global endeavor to develop surgical care. The ACS Operation Giving Back and the Committee on Trauma provide practice guidelines and standards and actively seek to build long-term relationships with local medical schools, hospitals, and surgical societies.[104,105] Partnerships between NGOs such as the World Federation of Societies of Anesthesiologists and Laerdal Foundation have led to funding for the assessment of global surgical capacity.[106] Wellcome Leap has $50 million available for programs that aim to double the surgical workforce in the next decade.[107]

From the perspective of academic medical centers, funding academic partnerships in a time of shrinking revenue is challenging. Support must come from a combination of nonclinical revenue dollars, research funding, international agencies, philanthropists, and industry. Global surgery–specific philanthropy is essential for academic medical centers to meet the financial outlay of sustainable, long-term capacity-building educational and research partnerships. The University of Utah Center for Global Surgery and UCSF Center for Health Equity in Surgery and Anesthesia have created seed grants from institutional and philanthropic sources to catalyze multidisciplinary projects that can then be funded by federal grants.

Global surgical research has been funded by the Fogarty International Center in the United States through training grants and various funding mechanisms for faculty. However, the Fogarty Center has the smallest budget of all of the institutes and centers at the NIH. Despite surgery's outsized impact on health both domestically and globally, there is still no home for surgery at the NIH. The NIH Research in the United Kingdom has set up a Global Surgery Unit, which has been catalytic in the breadth and scope of projects.

Nevertheless, while funding is and always will be a challenge, the momentum to address global surgical needs has grown exponentially through advocacy at every level. More recently, a team from the ACS has been lobbying the US Congress to include funding for neglected global surgical diseases in the annual budget to the State Department.

Pitfalls of Academic Global Surgical Partnerships

Many well-intended programs may ultimately fail because of well-known pitfalls. For institutions intending to engage in academic global surgical partnerships, the following essential discussion points must be addressed at the outset.

Failure to formalize the partnership: This is a formal MOU between partner institutions that must include the local institutions such as the Ministry of Health. It must set out the expectations of the partnership, roles, and responsibilities of collaborators, including authorship on any mutually developed publications, timeline, and funding. A transparent and formal agreement will engender trust, making any partnership more likely to be effective and protecting all parties involved.

Failure to invest in cultural competency: Before embarking on any work in another setting, learning about the culture and customs of the collaborators is critical, particularly when crossing racial barriers. Failure to understand local culture with prerequisite cultural humility will lead to perceived arrogance and failure to actualize the global surgical goal, even if it had the best of intentions. This applies domestically as well (see "Case Study from the United States").

Failure to actualize bidirectional benefits: Institutions that form self-serving partnerships resulting in an overwhelming unidirectional benefit, whether clinical exposure or research endeavors, ultimately will not last. Although having access to funding can contribute to an imbalance in power in a partnership, it does not equate to superiority, nor should it drive a unidirectional benefit strategy. The local institution must see the benefit of the collaboration, such as sustainable clinical care through the creation of surgical training programs, active engagement of local partners in research endeavors, and/or acquisition of research skills. Furthermore, failure to recognize, value, and incorporate local clinical, educational, and research priorities, regardless of the funding or priorities of the high-income partner, will result in programmatic failure. Equity and bidirectionality should be guiding principles for partnerships or risk engendering a feeling of neocolonialism.

Failure to maintain surgical standards: Surgeons have a strong desire to do good. Good clinical governance and continuous quality assurance are essential for developing sustainable surgical care delivery. With a poor surgical infrastructure in many parts of the world and a high disease burden in an environment of an inadequate surgical workforce, succumbing to poor standards and operating outside one's skill level or training is easy. Being the most qualified person present is not a justifiable reason for attempting a non–life-threatening intervention if not competent in it. Many local staff have the context expertise to deliver care in that setting, which visitors often do not. Unwittingly creating complications will not instill confidence in the partnership and can lead to a loss of credibility for the individual and the institution.

Political instability: Politics and economics usually intersect with global health. Most LMICs do not have the resources to invest in their healthcare system—the institutions of governance are weak; governments may be more dictatorial than democratic; and active repression, corruption, and malfeasance may be common. Political instability is a clear and present danger for staff within this context. Personnel safety is an essential concern for institutions developing partnerships in one or more LMICs. Institutional risk management, travel insurance, and evacuation plans must be determined ahead of time in case of threats to safety. Furthermore, plans to manage occupational exposure to HIV or other infections, including the ready availability of postexposure prophylaxis, should be considered as a part of planning. The greatest threat to any global program is a threat to life. Despite this, foreign staff should not add to the burden on already short-staffed local partners for urgent assistance in an emergency.

CONCLUSION

Global surgery is an inherently multidisciplinary and interprofessional field that is rapidly developing into systematic study and addresses the unmet surgical needs worldwide. Surgeons and their institutions have an opportunity to play a role in improving access to affordable, high-quality surgical care for most of the world's population and creating sustained impact for generations.

Case Study From the United States

The concept of global surgery has evolved to encompass every region and every country, affecting many vulnerable groups. From a local perspective, surgeons in the United States particularly need to be aware of the American Indians and Alaska Natives (AI/AN) who are a critically underserved population within the United States with substantial disparities in surgical outcomes.

Historically, colonization of the United States by European immigrants resulted in massacres, forced removals, and the introduction of new highly infectious diseases, ultimately upending traditional ways of life and knowledge of the native populations.[108] Tribal nations are physically located within the United States but are considered sovereign nations with self-determination and the authority to self-govern. Starting in 1787, the US Constitution recognized a growing relationship between the federal government and tribal nations. Many tribes were forced to sign treaties with the government in exchange for resources to allow their communities to exist.[108] These treaties initially helped, but subsequent reallotment and new laws resulted in further loss of land and natural resources.[109]

As of 2022, 9.7 million people identified as AI/AN in the United States alone or in combination with other racial groups (Fig. 15.8).[110] By the year 2060, the US AI/AN population is projected to represent 2.6% of the overall population.[110] Within the United States, there are 574 sovereign tribal nations and 334 federally- and state-recognized AI/AN tribes located across 35 states.[109] AI/ANs possess reservation and trust lands encompassing 100 million acres of land mass, mostly located in remote and underdeveloped areas and large enough to essentially be the fourth largest state in the United States.[111]

Compared with the rest of the United States, AI/ANs experience higher poverty rates (26.8% vs. 4.6%).[110] They are younger than the overall population (median age 32.9 vs. 38.5), with 29% younger than 18 years.[110] They have the lowest life expectancy in the United States at 5.5 years shorter than other groups.[112] They have a higher prevalence of chronic diseases and unintentional injury.[113] They tend to have poor access to healthcare. In 2019, 51.9% of AI/ANs had private health insurance, 42.1% relied on public health coverage, and 14.9% had no insurance coverage.[114] Various sociocultural and physical barriers contribute to these barriers to healthcare, including health literacy, limited English-language proficiency, differing communication styles, traditional beliefs, remote locations, long travel distances, lack of transportation, difficulty accessing healthy food, and mistrust of westernized medicine from historical trauma.

Surgical outcomes in this population have been poorly studied but demonstrate substantial disparities compared with the general American population.[115–117] AI/ANs have higher rates of injury, mortality after injury in both adult and pediatric age groups, and poorer access to postacute care services after discharge. This population also has inadequate access to surgical care for various cancers. They are more likely to be diagnosed at a later stage,[118] are less likely to have cancer surgery than the

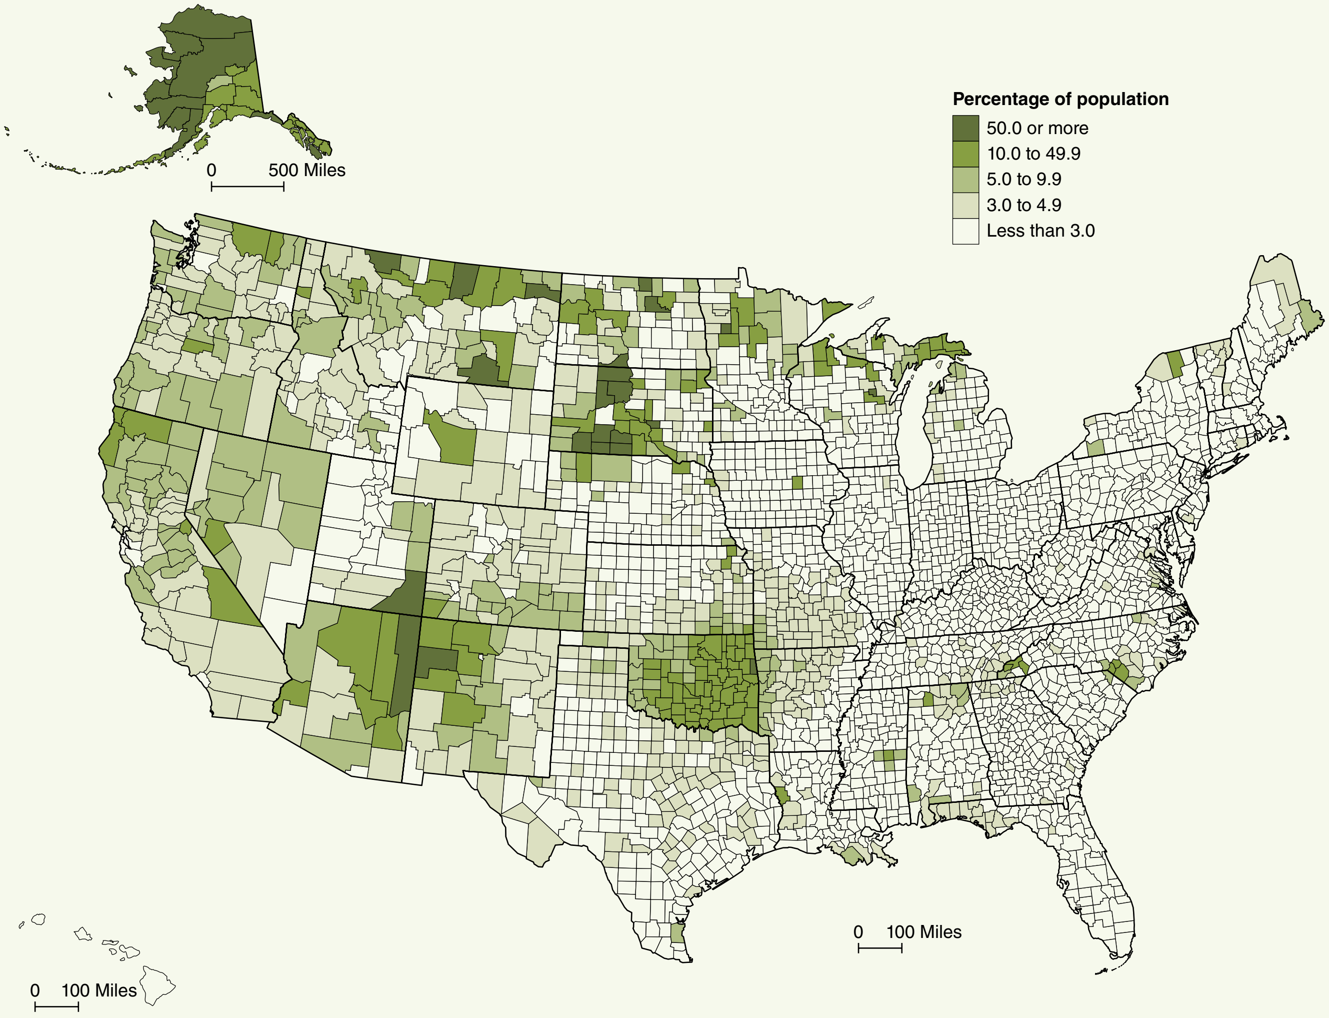

FIGURE 15.8 Distribution of American Indian and Alaska Native Population across the United States. Map lines delineate study areas and do not necessarily depict accepted national boundaries.

general population, and are more likely to have emergent surgery for cancer care and longer hospital stays when undergoing cancer surgery.[119] They are less likely to receive adjuvant chemotherapy and radiation for common cancers and less likely to receive cancer care concordant with established guidelines and shorter survival.[120]

Healthcare for this population has evolved since 1824 when the Bureau of Indian Affairs was formed in 1824 under the US War Department to contain infectious diseases among tribes close to military posts.[121] In 1959, this evolved into the Indian Health Service (IHS), a US federal government agency under the purview of the US Public Health Service. The Indian Health Care Improvement Act of 1976 made Medicare and Medicaid services reimbursable through IHS and tribal healthcare facilities, which helped secure better access to healthcare for AI/ANs, and this access was made permanent with the passage of the Affordable Care Act in 2010.[109]

The IHS provides health services to approximately 2.6 million AI/ANs through government-operated hospitals, tribally operated hospitals, and urban health clinics.[109] To receive inpatient, ambulatory, emergency, dental, and preventative health services, IHS patients must be members of federally recognized tribes.[122] Only a limited number of IHS facilities offer general surgery capabilities, and specialty care requires unique referral processes with strict eligibility criteria. Throughout history, federal policies sought to forcibly assimilate AI/ANs through boarding schools and physical relocation of tribes from reservations to urban areas through government relocation programs affecting their eligibility for healthcare through the IHS system.[123]

Because IHS is part of the federal government, its budget is included in a yearly request to Congress for approval, but it is poorly funded.[124] In 2020, the IHS had a fiscal year budget of $6.0 billion.[125] These funds are discretionary and not mandatory, such as for Medicare, and the IHS operates on an estimated 59% of resources compared with what other facilities need to operate.[126] In 2018, the IHS received approximately $4000 per person to provide services for the AI/AN population, which is less than half of the per capita healthcare spending for US federal inmates and about a third of the expenditure for the general US population.[126] This largely translates into limited human and infrastructure to provide services. The IHS has high physician vacancy rates (29%–46%) due to geographic isolation, lack of housing, lower salaries, burnout, and lengthy hiring processes, even though the IHS offers loan repayment programs, scholarships, and university fellowship program partnerships to increase these numbers.[126]

Surgical systems for this vulnerable and underserved population in the United States are woefully inadequate. The AI/AN population is increasingly included within American global health programs as an example of local health disparities that need urgent attention.

ACKNOWLEDGMENTS

The authors wish to thank Hafsa Zahid for her work on assembling this chapter.

Conclusions

ETHICAL FOUNDATIONS FOR SURGEONS

Moral philosophers consider ethics to be the study of right and wrong conduct. Surgeons are regularly placed in the position of needing to make decisions about what is best for their patients. Often these decisions require input from the patients and are thus shared decisions. However, frequently surgeons must make decisions on their patients' behalf without their patients' input. Consider the many intraoperative decisions that a surgeon must make in moving through a procedure. These decisions require judgments about what is optimal or most efficient (and thus "right") even though those decisions are not moral or ethical decisions. In the upcoming section, we will focus on the decisions that surgeons must often make with and on behalf of their patients on explicitly ethical topics for which it is often less clear what is the best or optimal decision. Although it is not possible to describe an entire ethical theory in the next several pages, we aim to explore how ethical principles can be used to clarify the choices that must often be made in the ethical dimension of surgical decision-making.

Principles of Ethics

Although many theories of ethics have been described over the last few hundred years, the four principles of medical ethics described by Beauchamp and Childress have been widely adopted as helpful over the past several decades.[1]

Perhaps the most widely used ethical principle in contemporary medical practice is respect for autonomy—that is, the autonomous choices of persons should be respected. It is essential to note here that we need not respect choices that are made by those who are not autonomous persons. For example, one need not go along with the choices expressed by someone who is clearly intoxicated. Another way to describe this principle is as the principle of "respect for persons."[2] In contemporary medical care, the choices of autonomous persons are given great respect. However, as will become evident in the following paragraphs, there are limits to respecting all of the choices of autonomous patients.

The second principle that must be examined is beneficence—namely, the requirement to do good for patients. As widely described, physicians have an ethical responsibility to make decisions that are beneficial to their patients. The practical application of this principle is readily apparent if one considers why a surgeon would recommend intervening to treat a patient exsanguinating from a stab wound to the neck. Even without discussion with the patient, we know that it is good for patients to keep them alive, and thus, we intervene in emergency situations on a regular basis to benefit patients. In fact, as will be addressed more fully later, the very concept of "presumed consent," often used in trauma cases, is based on the assumption that patients would want us to save their lives and derives from the principle of beneficence. As one can readily see, this principle does not define benefit, and the challenges of how to define what is good for patients are often contentious issues in clinical practice.

The third principle often used in ethical decision-making in medicine is nonmaleficence, or the duty to avoid harming patients. Many surgeons are familiar with the paraphrase of the Hippocratic Oath that doctors "should at least, do no harm." This idea of avoiding harming patients is the basis for nonmaleficence. Note that the concept is "nonmaleficence" rather than "nonmalfeasance," which is a legal term rather than an ethical concept.

The fourth principle that frequently is raised in clinical ethics is justice—that is, treating people fairly and equitably. This final principle is somewhat different from the others in that it refers not only to the individual patient but also to how that patient is treated relative to other similarly situated patients. As a principle, justice is the imperative to treat people fairly whenever possible. Although not uniformly valued as an ethical principle in the history of surgery, it is now accepted to be a foundational principle.

With these four widely recognized ethical principles now defined, it is often tempting to place them in a hierarchical arrangement, with the first being the most important and the fourth being the least important. However, such a strict ranking is not acceptable. Rather, the principles must be considered as a group and applied as appropriate to each specific case. In contemporary medical ethics, perhaps the greatest ethical issues surround how to balance the autonomous choices of patients with what physicians consider to be beneficial for their patients. For example, consider a patient with widely metastatic anaplastic thyroid cancer. We know that this patient will not benefit from any surgical attempt to remove their tumor because the metastatic disease will progress rapidly regardless of the attempted surgery. Such a patient may ask a surgeon to operate and remove their thyroid cancer. Even though the request might be made by an autonomous person deserving of respect for their choices, nevertheless, the surgeon should decline based on the principles of beneficence and nonmaleficence. In cases of widely metastatic anaplastic cancer, to attempt a large surgical resection of the primary would not help the patient (and might even harm the patient). Thus, in such a case, beneficence and nonmaleficence would appropriately be prioritized ahead of respect for autonomous choices.

Consider an alternative situation in which a patient is diagnosed with ductal carcinoma in situ. Assuming that it was appropriate from a medical point of view for this patient to have either a lumpectomy or a modified radical mastectomy, the patient's choice should be respected. Even if the surgeon believes that having a smaller operation might be better, we allow the patient to define what is better for them and thus abide by their decision rather than arguing based on beneficence to override the patient's choice. Thus, it is important for surgeons to understand that when there are multiple medically acceptable options, it is the patient whose preferences are most important rather than the surgeon's assessment of what is "best."

Virtue-Based Ethics Approaches

Although the principle-based ethical analysis outlined in the paragraphs earlier is commonly used in clinical ethics decision-making, it is valuable to also realize an alternative approach to ethical decision-making. Virtue-based ethical theories depend not on ethical principles, but rather on the quest to understand and live a life of moral character.[3] Largely derived from Aristotle and the ancient Greek philosophers, virtue-based ethical theories suggest that we should attempt to conceptualize how someone of high moral character would act and apply that approach. We will return to consider this approach to ethics in the later section on professionalism and how character development can lead to right actions.

Application of Ethical Principles to Central Issues in Surgical Practice

Having seen briefly how ethical principles can be used to analyze a challenging case, it is helpful to consider their role in elucidating several central ethical issues in surgical practice. Perhaps no topic more centrally focuses on the ethical dimension of surgical care than the concept of informed consent for surgery. Although seen as a central ethical tenet today, earlier generations of surgeons thought nothing of making decisions for their patients based on what was best from a purely medical perspective regardless of the patient's preferences.[4] Today, we accept that, based on respect for patient autonomy, patients should have the opportunity to make choices about their own bodies. Thus, if a patient has the capacity to make decisions—meaning that they are autonomous agents—then the surgeon must obtain the patient's permission before operating on them. The requirement for the patient having the capacity to make decisions is the reason why we do not explain operations to comatose patients, but rather find surrogate decision-makers in those circumstances.

Informed Consent

Once we have determined that the patient has the capacity to make decisions, for informed consent to be valid, the patient must have the opportunity to hear the risks, benefits, and alternatives to the recommended operation.[5] This discussion will not come as a surprise to any surgeon. However, is the surgeon's ethical responsibility to tell the patient the risks, benefits, and alternatives or only provide that opportunity to be informed about these things? In other words, can valid informed consent be obtained from a patient who declines to be informed? We argue that based on the fundamental principle of respect for patient autonomy; the ethical responsibility is to give the person the chance to be informed, not to recite information against the patient's wishes. To provide detailed information to a patient who wants to completely depend on the surgeon to make a recommendation without more background knowledge from the surgeon would be to override the autonomy of the patient.

As noted earlier, in emergency situations when a patient lacks capacity to give consent, rather than finding a surrogate decision-maker, physicians will intervene based on "presumed consent."[6] Thus, rather than ignoring the principle of respect for autonomy, when the patient cannot make their own choices and there is not time to find a surrogate decision-maker, the decision to treat the patient is based centrally on beneficence—namely, the importance of keeping the patient alive.

Innovative Procedures

Although not commonly an issue in the everyday practice of most surgeons, occasionally, surgeons are in the position of obtaining informed consent for operations that have not been done before or were only done a handful of times previously.[7] Obtaining informed consent for innovative operations is a particular challenge in that if an operation is truly innovative, then the surgeon often does not truly know what the risks are. In such situations, how can a discussion of risks occur when the surgeon is unsure what the risks are? We believe that in such situations, the principle of respect for autonomy clearly outlines the value of disclosing the uncertainty of what are the true risks. Thus, if a surgeon is offering a patient an innovative operation, the patient must understand that it is innovative and that there is uncertainty about the risks. As hard as it is for many patients to accept uncertainty on the part of their surgeons, the surgeon should be forthright in describing what the risks might be but with full disclosure of the true uncertainty regarding those risks.

New Procedures for the Surgeon and the Learning Curve

Much as patients should be told when the risks of an innovative operation are unknown, so too, should a patient be clearly told if the surgeon lacks experience with even a well-accepted operation.[8] Consider the discussion around a robotic approach to resecting a lung tumor. Even if robotic approaches may be well described and even accepted as the standard of care in some situations, if I, as a surgeon who is late in adopting the robotic technique, am seeing a patient who might benefit from a robotic approach, I must disclose to the patient my lack of experience. Such knowledge is critical to the patient making an informed decision—that is, being treated as an autonomous person. Some surgeons have asked after how many operations is it no longer necessary to disclose one's relative lack of experience? Although there is not a clearly defined number for every operation, it certainly depends on the procedure and the surgeon in determining how steep the learning curve may be. Again, based on respect for autonomy, a general guideline would be that the surgeon should disclose their lack of experience until they are confident that a reasonable patient would no longer find that information useful in their informed decision-making.

Consent and Assent

One specific challenge that often arises in the care of children is how to manage the young patient who is not old enough to legally sign consents but certainly has the mental capacity to participate in decision-making. In such situations, ethicists often refer to the pediatric patient's agreement to have the operation as "assent" rather than "consent."[9] In such cases, even though the pediatric patient would not actually be giving consent for the operation, explaining the operation to the patient in a meaningful way so that the patient can express agreement with the operative plan is ethically appropriate and consistent with the principle of autonomy.

Decision-Making for Patients who Lack Autonomy

There are many situations when patients lack the ability to make decisions for themselves. As noted earlier, this may be the case when a patient lacks the mental capacity to appreciate their situation and make decisions either because they are very young children, intoxicated, suffering from a psychosis, or unconscious. Often with very ill surgical patients nearing their end of life, the patients are intubated and sedated and thus not able to participate in the decision-making.[10] In such situations, physicians go to surrogate decision-makers to make decisions. Who is the appropriate surrogate decision-maker? The answer depends on the situation and the applicable state laws. If the patient has assigned the surrogate decision-making role to a specific person by naming a durable power of attorney for healthcare, then the named individual is clearly the surrogate decision-maker and can make all decisions that the patient would have been able to make before losing capacity. If there is no formally designated surrogate decision-maker, then the "next of kin" is usually the appropriate person to make decisions. For children, this is most commonly a parent. For adults, if there is a spouse, then the spouse is the default surrogate decision-maker. In situations in which there is no spouse or "significant other," then the children or parents of the patient may be appropriate surrogates depending on the case.

Best Interests and Substituted Judgment

It is essential to note that if a patient is making a decision for themself, then the patient can define what constitutes benefit. If, however, a surrogate decision-maker is making decisions on behalf of the patient, then the question of what the basis is for deciding what is best for the patient remains. Two important concepts play a role in this setting. In patients who have previously had the chance to make their preferences known, the surrogate should make decisions based on substituted judgment—that is, what the patient would have wanted to do. However, if the patient has never been able to express their wishes (e.g., for infants, young children, or those lacking the intellectual maturity or capacity to make decisions), the surrogate decision-maker should make the decision for the patient on the basis of what seems to be in the patient's best interests.[11] Both substituted judgment and best interests can be challenging to define because there is not commonly a single answer.

The Challenge of Futility

In some cases when a patient is very sick and the prognosis is very poor, physicians may refer to ongoing active treatment of the patient as being "an exercise in futility." It is valuable to consider the concept of futility separately as it is one that, although widely used in describing end-of-life treatment, is not well defined. If one thinks of how patient decisions were routinely made 60 to 70 years ago, it is evident that "the doctor knows best" was widely accepted. Physicians made decisions for their patients based on the medical knowledge that the physician had and the patient lacked. This traditional approach to medical decision-making can be characterized as paternalistic. It clearly is in contrast with the high level of respect for the autonomous choices of patients that characterizes contemporary medical decision-making. An exception to the high degree of respect for patient choices is the situation when a patient or surrogate requests a futile treatment. The argument is that physicians are only ethically obligated to provide treatments that have a reasonable chance of success. By definition, physicians do not have to offer futile treatments, and thus, any request for futile treatments can be denied. As is readily apparent, calling a treatment an "exercise in futility" or "futile" thus takes the choice away from patients or their surrogates.

The biggest problem with use of the concept of futility in this manner to pull control of decision-making away from patients or their surrogates is that there is no objective definition of futility.[12] In fact, something can only be called *futile* relative to the goal of the treatment. For example, if a 92-year-old patient who is bedbound secondary to advanced dementia and ischemic bowel after an emergent abdominal aortic aneurysm repair is thought to need a total abdominal colectomy, some might argue that such aggressive treatment in this patient is an exercise in futility because it is so unlikely to lead to the patient's long-term survival. However, if the goal were actually just to keep the patient alive long enough for grandchildren to assemble at the bedside, one might consider surgery (even though still very high risk) nevertheless reasonable relative to the goal of the intervention. We believe that rather than trying to pull the locus of decision-making power away from patients by calling some interventions futile, physicians would be better served to simply state that the intervention is unlikely to lead to the desired goal and thus is not recommended.[13]

FOUNDATIONS OF PROFESSIONALISM IN SURGERY

Having considered the fundamental principles of medical ethics and their specific relevance to surgical practice, it is now helpful to explore the concept of professionalism in surgery. At the outset, rather than taking an approach to this topic that focuses on "professionalism" as a concept that might be examined with detachment, this discussion will focus on what it means specifically in the surgical context to *be* a professional. Hence, although we will want to outline some of the historic constructs that define professionalism in medicine in general and surgery in particular, this discussion will also focus on how a professional might be formed and what it would mean to become one.

The historic foundations of the concept of professionalism are commonly traced back to early statements of the qualities ancient societies expected of those who professed to have the knowledge, skills, and personal attributes to be entrusted with the care of the sick. The vulnerability of the patient in such a relationship was recognized, and regulations of the early medical profession to protect the patient's interest in that context were embodied, for example, in the Code of Hammurabi, in which 9 of the 282 laws prescribed specifically pertained to surgical practice.[14] A fuller and more commonly referenced ancient codification is contained in the Hippocratic Oath, which established principles on which the profession was to be founded.[15] Included among those was a commitment to the patient's good, including protection from harm, an obligation to preserve and not actively terminate life, the guarding of patient confidentiality, the avoidance of sexual misconduct in the physician-patient relationship, a commitment to teach the next generation and honor one's own teachers, and divine accountability for all of this, among other precepts. Importantly, these qualities implied an underlying and specific rather than vaguely virtuous character foundation for the professional. Furthermore, these qualities were seen as of such importance that they were enfranchised as obligations to which the physician bound themselves on oath and with affirmed consequence. For the purposes of the present discussion, one might accordingly begin with the premise that the physician and surgeon, from ancient times, has been seen as holding a position of public trust and intimacy that necessitates the highest levels of integrity, commitment, and accountability. Furthermore, the physician has always been regarded as part of a moral community committed to the upholding of these standards (i.e., the field of which they as a professional are a part).

From a modern sociologic perspective, a profession has been defined as an entity having "[a] professional association, cognitive base, institutionalized training, licensing, work autonomy, colleague control, . . . [and a] code of ethics."[16] Similarly in recent surgical education summations, the pillars of the profession have been defined as including a vocation (calling) associated with advanced knowledge, skills, and competence and a commitment by every member to the greater public interest.[17] Modern iterations of the specific standards of the medical profession and its attendant definition of professionalism have been offered by multiple associations and boards.[18–22] These contemporary outlines, like their ancient counterparts, embody the critical relationship between outwardly manifested and observable behavioral standards upheld by the profession and the character-based or internal qualities of the individual professional.

Before moving on from the theme of definitional frameworks of professionalism, it is worth noting that the qualities so enumerated have been seen by thought leaders over recent history as predictive of success in the profession of surgery.[23] Specifically, sincere compassion for patients, integrity, active engagement in improvement, and commitment to lifelong learning were recognized as inherent qualities of the effective or successful surgeon. Additional qualities receiving increased emphasis in more recent history included humility, inclusivity, and collaboration.[23,24] Although these characteristics might be seen as foundational for any professional, there may be reasons they are particularly relevant to the field of surgery. Surgeons engage with patients in a problem-solution encounter predicated on the following question: "How may I help you?"[25] Furthermore, because their work often involves direct and potentially harmful bodily intervention and entrustment of care under sedation or anesthesia, surgeons function in a unique fiduciary role in relationship to the life of another. In no other discipline, nor to the same extent, does one person assume such direct and embodied responsibility for a fellow human's life and well-being. As such, the surgeon may rightly be seen as the most entrusted and privileged and, accordingly, most obligated and duty-bound of professionals.

Professionalism Frameworks and Teaching Professionalism

As already alluded to, the relationship between professionalism—the behaviors or qualities that are upheld and enforced by the profession writ large—and a professional—the individual practitioner expected to cultivate, exhibit, and embody those qualities at the bedside—is integral to the translation of the standards of the profession into its collective practice. Furthermore, the conceptual framework through which the profession sees that relationship ends up defining its educational strategy to inculcate its standards in the next generation of practitioners. In this regard, three dominant frameworks for professionalism have been described: virtue-based professionalism, behavior-based professionalism, and professional identity formation (Table 16.1).[26]

In reviewing these frameworks, it is apparent that the models are not mutually exclusive, and they emphasize potentially complementary aspects of human sociology, psychology, and personhood. Accordingly, regarding a virtue-based approach, humans do not willfully engage with or specifically sacrifice their own advantage or interest for causes they do not see as fundamentally correct, true, and right. Our mouths speak from the overflow of our hearts or inner worlds, and from that foundation we act as well, especially under pressure. To that end, teaching a professional to cultivate an internal world founded in and ordered toward compassion, empathy, humility, and service to others, with an attendant sense of meaningful accountability for those qualities that extends beyond personal advantage or secondary gain, is of obvious importance. Developing such instinctive inclinations allows those desirable professional qualities to be manifest as habituated responses in the context and pace of daily work, where time and space constraints preclude deliberative moral reasoning. Similarly, because part of accountability and orientation of effort involves clarity of standards and feedback that reinforces desired behaviors and redirects counterproductive ones, a behaviorally based strategy provides an external scaffold around which to organize attention and effort stemming from internal motivation. Behavioral approaches can help provide a shared mental model of the desired outputs of more internal and observationally occult processes and hold us responsible for their outward manifestations. Finally, being social creatures, the identity formation model recognizes that neither our internal worlds nor our outward behaviors incubate in a vacuum, but rather are themselves impacted in profound ways by our social and relational contexts. Magnifying desired behaviors by highlighting effective role models, examining their behaviors, and exploring their "habits of the heart" in a deconstructive fashion that renders those internal elements accessible to learners may be one of the most effective strategies for equipping trainees in the practice of professionalism. Such approaches also allow learners to see professionalism not just as a theoretic construct, but rather a praxis, much like their practice of surgery itself. Identity formation strategies also provide a means of uncovering the "hidden curriculum" that positively and negatively governs professional formation in ways much more powerful than curricular effort alone.[27] Taken together, these frameworks provide a rich matrix through which to view an individual surgeon's lifelong professional journey and a multifaceted approach to its development and maintenance.

Contemporary Challenges in Cultivating Professionalism in Surgery

Despite a proliferation of literature and statements around the theme of professionalism in recent years, medicine in general and

TABLE 16.1 Comparison of Professionalism Frameworks

FRAMEWORK	FOCUS	ASSUMPTIONS	STRENGTHS	RECOMMENDATIONS
Virtue-based professionalism	Character, moral reasoning, and humanism	Appropriate action results from internalizing the right values until habituated	Prioritizes internal values and motives, routinizes moral reasoning	Internalize and commit to core values and actions guided by moral reasoning and reflective practices
Behavior-based professionalism	Behaviors, milestones, and competencies	Appropriate action results from clear expectations, feedback, and external reinforcement	Defined end points, focus on directive feedback, evaluates competence	Outline expectations, teach to behavioral end points, reinforce correct and sanction unprofessional behaviors
Professional identity formation	Evolving identity with capacity for change	Appropriate action results from identify formation via socialization in a community of practice	Describes the developmental trajectory of identity formation and socialization into the profession	Provide positive role models and sensitize learners in advance to potential negative role modeling situations

Adapted from Irby M, Hamstra S. Parting the clouds: three professionalism frameworks in medical education. *Acad Med.* 2016;91(12):1606-1611.

surgery specifically continue to struggle with consistent achievement of the standards so articulated. Recent studies have suggested that although most providers behave professionally, over 60% of healthcare workers experience unprofessional behavior regularly, including in the perioperative context.[28,29] Trainees are frequent targets of unprofessional behavior, including bullying, discrimination, and harassment.[30] Prior studies have suggested that surgical residents with performance issues during their training have professionalism challenges as a predominant and early manifestation and that, unfortunately, these issues are typically still present as they complete training.[31] For surgeons in particular, unprofessional behavior has been shown to correlate with themes including a culture of safety, teamwork, and, ultimately, patient outcomes.[32] Thus, although increasing attention has been given to the theme of professionalism in medicine and surgery in recent history, the presence and impact of continuing lapses on the training environment, trainees themselves, and patients demonstrate an ongoing and unresolved challenge.

Beyond these challenges inherent to the profession itself, it is worthwhile to consider an underlying issue that both our profession and society wrestle with—the challenge of establishing consensus around values and norms in a pluralistic cultural context. As the world has become smaller through mass communication and the mixing of historically segregated cultures and worldviews, contemporary societies have struggled to facilitate constructive dialogue around themes of morality and shared values. Under the ensuing influences of contemporary thought and the apparent benefits of empiric methodology in many realms of human endeavor, ethics as a field has tended to focus less on historical considerations of what is good and right and pivoted to an increasing emphasis on process and methods of inquiry that attempt to mimic scientific approaches to human knowledge. As a result, modern ethics and the related notions of morality on which it is based, including in the professional and specifically medical domains, has increasingly tended toward an agnosticism that is preoccupied with language, subjective analysis, and explorations of power and manipulation, rendering the concept of moral knowledge or “rightness” in much of academic discourse of diminished clarity and even perceived relevance.[33] In such contexts, particularly in the West, notions of individual freedom and autonomy have gained ascendance in ethical and professional deliberation, given their capacity to accommodate, though not necessarily constructively resolve, pluralistic and even conflicting standards for professional action. In such contexts, some ethicists and professional leaders have advocated that physicians should conduct themselves as providers of a service whose accountability is to the autonomous right of the individual patient within the context of professional society ethical statements, rather than to the individual professional’s sense of their own moral obligations.[34] Debates about the related right of conscience of the professional or whether such should even be countenanced as an issue ensue,[34] with resulting potential for moral incongruity, if not injury, inherent to the profession’s expectations of the professional.

These broad cultural trends present critical themes that will continue to require focus in discussions of surgical professionalism in the future. These include how to prioritize patient autonomy, need, and social justice, including access and resource allocation, in the face of expanding options in care. Balancing professional societal statements voicing majority opinions with dissenting individual and minority perspectives that challenge such, thereby maintaining vigilance around the errors of omission and even commission medicine has historically and indeed presently shown itself capable of, is an additional theme of importance. Finally, defining the implications for physician motivation and burnout if a practitioner is required to subordinate their conscience and related sense of meaning and purpose to individual patient or societal norms or priorities will be necessary.

It is beyond the scope of this discussion to adequately address all these themes, but it would be inappropriate to not offer a perspective on how they might be approached by the profession considering such surrounding trends. In this specific context, the field of ethics as a discipline that provides guiding principles upon which we can discuss issues of uncertainty and disagreement may provide a foundation for constructive dialogue. Thus, particularly in the present historical moment, embracing the principled approach offered earlier in this chapter as a framework through which to conduct crucial conversations with patients, families, and colleagues can be a way for a professional to present themselves, to listen, and to articulate their own values as a manifestation of professional practice and personal integrity. Allowing differing perspectives to be expressed in the context of a collective commitment to beneficence, nonmaleficence, autonomy, and social justice provides a framework for agreement on common motives, prioritization of patient- and population-centered priorities, and constructive expression of disagreement where that persists. Seen through such a lens, the practice of medical ethics becomes not only a means of making challenging decisions but also an avenue for understanding and transparency in areas of importance but diversity of opinion within the profession. Through this type of dialogue, we can iteratively define, revisit and refine, correct, articulate, promulgate, and enforce the core standards of the profession in the face of the evolving tools, opportunities, limitations, and liabilities of the practice environment. Accordingly, appropriate application of the principles of medical ethics to the challenges of our times becomes one of the hallmarks of the professional, who uses these principles to honor the perspectives and common commitments, even in disagreement, that govern professional behavior.

Professional Identity Formation and the Future of the Profession of Surgery

In concluding this review of professionalism in surgery, we would like to return to the theme of how one becomes, or is formed and potentially re-formed when necessary, not just a member of a profession but a professional themselves. T.S. Eliot once said that contemporary human effort had oriented itself to finding ". . . systems so perfect that no one will need to be good."[35] Professionalism framed as a list of desirable behaviors may enable teaching and assessment as part of a behaviorally oriented approach. However, if not accompanied by a robust model for the personal development and formation of the individual surgeon to themselves be a professional, such outside-in approaches will falter, for it will take professional people to deliver these standards at the bedsides and in the operating room. Whether we like it or not, we as surgeons are the vehicles through which patients, families, and colleagues experience either professional standards or their deficiencies. In concluding this chapter, we will accordingly consider a strategy for such formation.

In pursuing this goal, it is apparent first and foremost that professionalism must be seen not as a list of qualities, but a belief system that motivates and internally drives the practitioner and the profession to standards worthy of the public trust.[36] Human beings do not ultimately act in a way that is inconsistent with their fundamental beliefs about reality, especially under pressure. As individuals and collectively as a profession, our organization and delivery of healthcare will ultimately spring from the beliefs we hold, be they consciously considered and presented or subconscious and occult, while nevertheless still directing our actions. The necessity in current debates is therefore not to critique and abandon historical oaths and belief systems so that we can enter a detached and agnostic space that is free and open in directing our actions under the influence of new societal and practice pressures. Rather, it is to define what the beliefs we are acting upon in fact are, to call them out and examine them for their fruit in our behaviors, and then reexamine them in the light of the product. For the surgeon specifically, such framing elevates our values and related ethics to the same level of importance as our foundational cognitive and technical skills, which in fact they are. Indeed, sociology has defined our belief system as one of the three key "logics" by which we can organize our delivery of goods and services, alongside markets and bureaucracies.[36,37] It also forces us individually and collectively through reflection and declaration to be transparent regarding our points of accountability in stewarding the public trust, without which the notion of our individual and collective professional identity dissolves.[36] In defining then the first signpost on the journey to becoming a professional, the surgeon individually, and all of us collectively, must be committed to the ongoing consideration of the fundamental beliefs about the why, what, and how of our professional praxis.

Second, such a belief system must again be embodied in the professional themselves. Prior authors[38,39] have highlighted that such a view of the professional emphasizes an additional highest level to Miller's Pyramid, where identity, or who one "is," crowns the process of knowing, knowing how, showing how, and doing (Fig. 16.1). Emphasizing the surgeon's identity has relevance for issues fundamental to human motivation, including autonomy, aspiration to mastery, meaning, purpose, fulfilment, and sustainment in the face of practice pressure. Furthermore, it moves the foundation for professionalism from another set of expectations with which to comply and called upon when necessary to the realm of personal presence out of which instinctive actions flow. As others have observed, this foundation provides a much more entrustable basis for consistency of professional action in the face of the ". . . uncertainties that underscore clinical decision making and the ambiguities that permeate medical practice, [which] require a professional presence that is best grounded in what one is rather than what one does."[40]

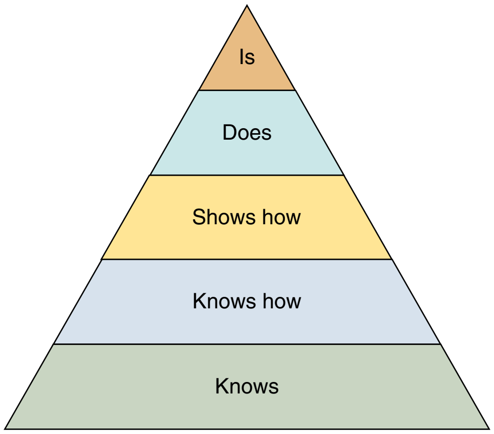

FIGURE 16.1 Adaptation of Miller's Pyramid highlighting identity as apex. (Adapted from Cruess R, Cruess S. Amending Miller's pyramid to include professional identity formation. *Acad Med.* 2016;91:180-185.)

Finally, models of personal formation should be used in developing the professional. Medicine has much to learn from spiritual and other models in this regard, unfortunately from which it has in many ways distanced itself in modern times. Military training and political movement strategies are other contemporary examples of formation-based strategies in personal and social group development. Formation in the medical context has been defined as ". . . the ongoing integration of an individual, growing in self-awareness and in recognition of a life of service, with others who share in the common mission of a larger group."[41] Spiritual and psychological models have identified several key steps in the formation process, which include the establishment of a vision or aspiration for what one is to become (often achieved through role modeling), intentional commitment to that vision that directs personal effort, and habituation through disciplines of embodied practice.[42,43] Formation can be used not only for initial development but also for remediation and re-formation, and accordingly represents a dynamic rather than static process. The Dreyfus model of formation pertains in this regard, describing how a professional progresses from rule-based behaviors as a novice to more nuanced decision-making in more complex situations, and ultimately creative problem solving in novel environments as mastery is pursued.[41,44] Key elements that support such processes in specifically medical contexts include the use of foundational narrative, the creation of a community of learners, and fostering of reflective practices.[41] The community element, in particular, lends itself to not only role modeling, demonstration, and development but also to sustaining and corrective influences without which effective initial trajectories may detour under the pressures of career progression. As such, the formation model emphasizes lifelong learning and accountability as inherent qualities and commitments of the professional.

In concluding this consideration of professionalism, two strategies demonstrating how one might use formation as a tool for developing the surgeon as a professional are offered. The first is that of appreciative inquiry. Learners can themselves be engaged in identifying faculty mentors who embody specific competencies, and those exemplars can then be affirmed and celebrated by inquiring into their personal habits foundational to that competence. Sharing those practices with learners becomes a way of embodying the competencies in persons and delineating behaviors that trainees and colleagues can adopt to support their own professional journeys.[45] Such approaches generate relevant narrative, invite reflection, and accentuate community as a foundation for learning consistent with the formation model. A second tool that has been effective is the use of book clubs involving trainees and/or faculty to promote reflective activity on themes of professional virtue and leadership (defined as influence for good) in the community of learning and practice context.[46] Such strategies, like the foundational ethical principles previously described, create a framework and context for constructive and diverse dialogue around themes of challenge, meaning, and importance and contribute to individual and collective growth by creating an intentional space for professional formation. By engaging in such activities, we as surgeons can fulfill our responsibility as eloquently described by Miller: "If we are to be faithful to the charge placed on us by society to certify the adequacy of clinical performance . . . then we can no longer evade the responsibility for finding a method that will allow us to do so."[47]

CONCLUSIONS

Ethics and professionalism are fundamental and closely related qualities of the effective surgeon. An understanding of foundational ethical principles anchors physician behavior and decision-making in a fashion that stewards public trust, orients behavior in complex contexts, and establishes a safe environment for constructive dialogue and consideration on issues of uncertainty and even disagreement. Professionalism describes the qualities an individual surgeon, and the collective profession itself, commits to in that same context of stewardship. Although these capacities can and should be viewed as a collective responsibility of the house of surgery and medicine in general, their effective delivery requires that they not only be standards of shared aspiration but that they also become embodied in individual practitioners as persons. Hence, the surgeon must endeavor to not only exhibit professionalism and ethical practice but also take on the identity of a professional themselves.

CHAPTER 17

Surgeon Health: Ergonomics

Yewande Alimi and Geeta Lal

OUTLINE

Introduction
  Burden of Musculoskeletal Disease Among Surgeons
Risk Factors for Musculoskeletal Injuries Among Surgeons
Consequences of Poor Ergonomics
Strategies to Improve Surgical Ergonomics
  Surgical Ergonomics for Open Procedures
  Surgical Ergonomics and Laparoscopic Surgery
  Surgical Ergonomics and Robotic-Assisted Surgery
  Surgical Ergonomics and Endovascular Procedures
  Surgical Ergonomics and Gastrointestinal Endoscopy
Additional Intraoperative Considerations
  Optimal Use of Adjuncts
  Antifatigue Mats and Footwear
Approach to Prevention of Injury
  Office Ergonomics
  Surgical Culture and Organizational Responsibilities
Summary

INTRODUCTION

The term *ergonomics* is derived from the two Greek words *ergon,* which means "work," and *nomos,* which means "natural law." The International Ergonomics Association defines ergonomics (also known as *human factors*) as a "scientific discipline concerned with the understanding of interactions among humans and other elements of a system." The term is also used to describe "the profession that applies theory, principles, data and methods to design in order to optimize human well-being and overall system performance."[1]

Ergonomics/human factors has several domains. Physical ergonomics is primarily concerned with characteristics such as human anatomy, physiology, biomechanics, and anthropometry as they pertain to physical activity. The main areas under this domain include work-related musculoskeletal (MSK) disorders, physical safety, and health. The key focus of cognitive ergonomics is mental processes because they can affect interactions among humans and other elements of a system. This domain examines topics related to mental workload, decision-making, interactions between humans and computers, and work stress. In contrast, organizational ergonomics refers to the optimization of social and technical systems, including organizational structures, processes, and policies.

Although aspects of surgeon wellness, such as burnout and mental health issues, have received increasing attention over the past 10 to 15 years, concerns related to surgeon physical health have only recently been brought to the forefront. This chapter will focus primarily on physical ergonomics as it pertains to surgical work.

Burden of Musculoskeletal Disease Among Surgeons

The United States Bureau of Labor Statistics publishes data on nonfatal work-related injuries and illness in private industry every year.[2] In 2022, the healthcare and social assistance sector had the highest number of these injuries (665,300), far outpacing those sustained in other sectors like construction, retail, manufacturing, and transportation/warehousing. Despite the healthcare sector being a major risk factor for work-related injuries, data on these injuries among surgeons are scarce and largely limited to survey studies. In the largest meta-analysis available to date, which included data from 5152 surgeons over 40 studies, 68% reported generalized pain from operating. The most common sites were back (50%), neck (48%), and arm/shoulder (43%). In addition to pain, study participants also reported other work-related MSK symptoms such as fatigue (71%), numbness (37%), and stiffness (45%).[3] To put these numbers into perspective, 12-month prevalence rates of neck, shoulder, back, and upper extremity pain in surgeons were found to be comparable to that reported by unionized apprentice construction workers using the same standardized Nordic Musculoskeletal questionnaire.[4] The most common types of work-related injuries faced by surgeons derived from pooled prevalence estimates include degenerative cervical spine disease (17%), rotator cuff pathology (18%), degenerative lumbar spine disease (19%), and carpal tunnel syndrome (9%).[4]

Although surgeons have a significant burden of work-related MSK disease, <30% seek treatment, and <5% actually report injuries to their supervisors and organizations.[3] There are likely many reasons for this; however, it does point out that the data collected solely based on institutional reporting is likely to highly underestimate the true rates of work-related injuries among surgeons.

There are two additional points of note. First, work-related MSK symptoms and injuries occur in surgeons across all specialties, irrespective of type of practice (academic vs. private). Second, there are objective correlates for the statistics reported in the survey-based studies. In a study by Meltzer and coauthors, 53 surgeons representing 12 surgical specialties underwent continuous wearable posture recording using inertia monitoring units during a total of 116 cases.[5]

Overall, surgeons spent 65% of procedure time in ergonomically high-risk neck positions. High-risk positions for the torso and shoulders were observed during 31% and 11% of procedure time, respectively. In addition, surgeon self-reported pain was predictive of ergonomic risk ($P < 0.01$).

Surgical trainees also report significant rates of MSK symptoms from operating. Among a survey of 98 plastic surgery residents in Accreditation Council for Graduate Medical Education (ACGME)-accredited programs across the United States, 92% reported pain in the operating room.[6] Similar rates have been reported among general surgery trainees.[7,8] The most frequent sites of pain are similar to those reported by practicing surgeons including the neck, back, and extremities.

RISK FACTORS FOR MUSCULOSKELETAL INJURIES AMONG SURGEONS

There are a multitude of reasons for such high rates of work-related symptoms and injuries among surgeons. Some are modifiable, whereas others are not. The type of procedure has a significant bearing on risk of injury. Minimally invasive/endoscopic approaches have the highest odds ratios for pain at any site and fatigue when compared with open surgery.[3] Surgical work, by its inherent nature, frequently violates principles of good ergonomics. Surgeons sustain nonneutral postures and perform repetitive motions for prolonged periods, often without breaks. In addition, studies using the NASA Task Load Index demonstrate that surgery is associated with high workloads,[9] both physical and cognitive. This leads to higher baseline muscle tension and increased risk of injury. Surgical culture is another contributing factor, leading surgeons to push through, ignore their symptoms, or accept them as a part of surgical practice. Furthermore, unlike industrial environments, human anatomy cannot be redesigned to optimize the workspace. Patients are unique, and standardization of surgeons and tools is difficult.

A major contributor for surgeons' work-related MSK symptoms pertains to instrumentation. Surgical instruments are designed to meet regulatory requirements (e.g., the need for sterilization) rather than users' ergonomics and comfort. In addition, their production is geared to the most common sizes that most surgeons can work with. This is especially true for staplers and laparoscopic instruments. Instrument-related issues are therefore more likely to affect surgeons with smaller hand sizes and short stature such as female surgeons. A recent systematic review demonstrated that female surgeons have a far higher likelihood of MSK symptoms when compared with their male colleagues, regardless of specialty.[5] In fact, they are three times more likely to report issues with using surgical instruments, with laparoscopic instruments, endoscopes, and staplers being the most frequent culprits.[9,10] Objective data support this observation because female surgeons had a significantly higher firing of the upper trapezius, flexor carpi radialis, and extensor digitorum muscle groups (as measured by electromyography [EMG]) during laparoscopic surgery even after correcting for height.[11] Furthermore, the use of adjuncts like surgical loupes and headlamps has been independently associated with increased time in ergonomically unfavorable neck positions ($P < 0.0001$ and $P = 0.0071$, respectively), thus leading to pain and other MSK symptoms.[5]

Surgeons also face ergonomic challenges outside the operating room because the burden of documentation in the electronic medical records, often in common clinic spaces, subjects them to ergonomic strains commonly seen in office workers. Lastly, studies show that awareness of ergonomic injuries faced by surgeons and mitigation tactics is minimal, and very few training programs actually have formal or informal ergonomics curricula for their surgical trainees.[10] This is especially important because studies have also demonstrated that less experienced trainees and surgeons have greater injury and discomfort than their more senior colleagues.[12] This suggests that inexperience and/or anxiety may lead to more frequent ergonomic errors such as incorrect body posture or inappropriate grip of instruments, thus contributing to higher rates of injury.

CONSEQUENCES OF POOR ERGONOMICS

Ergonomic challenges not only lead to work-related MSK disease but also have other far-reaching consequences. Existing literature shows that approximately 12% of surgeons experiencing work-related symptoms will need a leave of absence, modify or restrict their practice, or retire early from a career-ending injury.[4] In a survey of the European Association of Endoscopic Surgeons, a significant proportion of the respondents (49%) felt their physical discomfort would affect career longevity.[11] This has enormous financial implications, both for the individual surgeon and their institutions. Additional studies show that persistent pain is significantly correlated with both professional satisfaction and self-reported burnout among surgeons.[11,13] Pain from operating has also been shown to affect several domains of surgeons' quality of life including sleep, concentration, patience, and relationships.[11,13–15] Given that there is an impending surgeon shortage in the United States,[16] this will no doubt affect patients' access to surgical care in the future.

In addition, surgeons' work-related symptoms have the potential to affect the quality of care and patient safety. Approximately 30% of surgeons report taking their own symptoms into account when changing the procedure they offer patients in order to reduce their pain.[3] The surgical stress-effects model, originally described by Chrouser and colleagues, provides a useful framework to understand how surgeons' symptoms can affect patient safety.[17] In this model, patient surgical outcomes are dependent on several factors including those intrinsic to the patient, team performance, and individual surgeon performance. The last element encompasses both technical and nontechnical aspects. Pain has the potential to affect nontechnical skills such as situational awareness, communication, teamwork, and decision making, all of which are the root cause of the majority of safety events in the operating room. Further studies are needed to determine if surgeons' work-related MSK symptoms have direct consequences on patient outcomes. Lastly, ergonomics-related issues are also affecting recruitment into surgery. A multi-institutional survey study of medical students reported that over one-third considered the physical demands of the job to be a common deterrent to pursuing surgical training.[18] The importance of this observation within the larger context of a looming surgeon workforce shortage for our aging population cannot be overemphasized.

STRATEGIES TO IMPROVE SURGICAL ERGONOMICS

It is important to note that even though the surgical work environment can be more difficult than that of an industrial worker, there are significant disparities between the application of well-known and accepted ergonomics principles in the surgical arena when compared with other workplaces. When looking at tactics to reduce MSK injuries in surgeons, there are several

TABLE 17.1 **Key Elements of Optimizing Surgical Ergonomics**

WITHIN THE OPERATING ROOM	OUTSIDE THE OPERATING ROOM
Positioning and setup	Preparation and recovery
Postural awareness and resets	Office ergonomics
Choice and use of adjuncts	
Breaks ± stretches	

elements to consider, both in and out of the operating room (Table 17.1).

The following sections provide a summary of best practices for intraoperative positioning, setup, and postural awareness for open, laparoscopic/endoscopic, and robot-assisted surgeries (RASs). Other resources for this include the American College of Surgeons (ACS) Ergonomics Taskforce recommendations and the Surgical Council on Resident Education (SCORE) curriculum module on Surgical Ergonomics.[19,20]

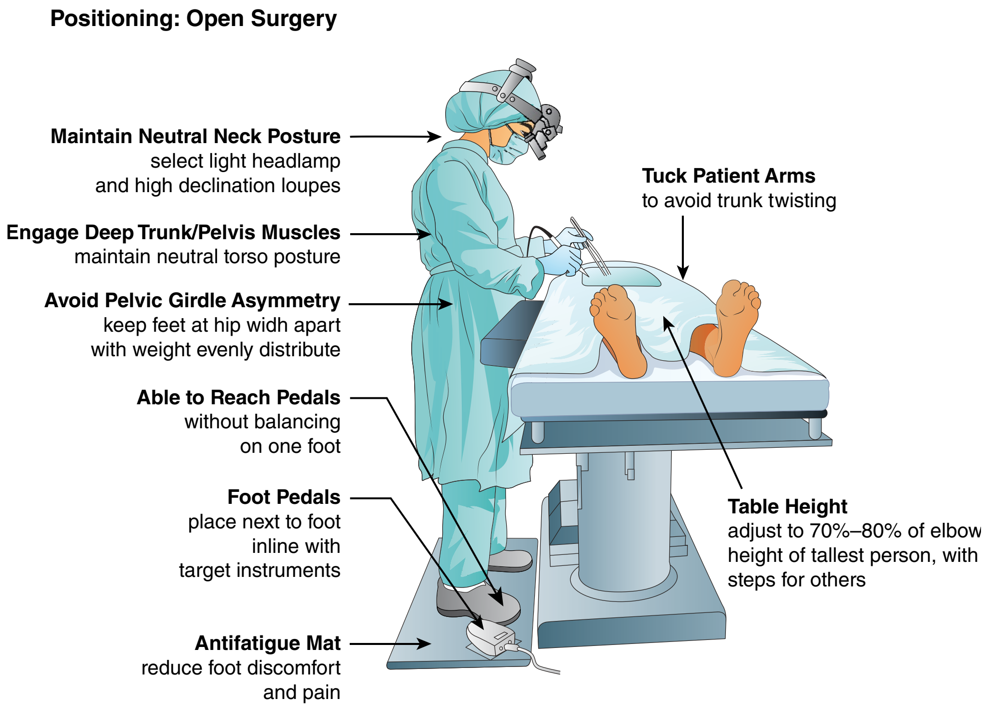
Surgical Ergonomics for Open Procedures

Overall, open surgery is considered more ergonomic than laparoscopic surgery because it allows direct visualization, greater range of motion, less confined postures, and ease of movement. However, it does have its challenges, and some data suggest that laparoscopic surgery actually reduces muscle strain in several upper body muscle groups in comparison with open surgery.[21] More recent studies using posture recording devices have confirmed that the highest postural neck risk for surgeons was during open versus laparoscopic procedures (adjusted odds ratio 31.1, 95% CI 8.47–114.41; $P < 0.001$).[5,22] Twisting of the surgeon's torso and extremes of neck flexion can lead in injuries such as degenerative disk disease, including herniations.

Proper setup of the operating room components is key to reducing strain and injuries. Operating room lights need to be positioned in the midline between the operating surgeon and the first assistant, rather than behind either of them.[19] When operating in a small space such as the neck, an ideal positioning of overhead lights would be such that one is right over the incision and another is directed toward it from the caudad position. It is important to tuck the patient's arms to the side to avoid trunk twisting. The operating table should be at elbow height and adjusted to the height of the tallest person, with steps for all other individuals. To maintain neutral surgeon posture, the shoulders should be directly over the pelvis and the legs a hip width apart, so as to distribute body weight evenly and engage the deep muscles of the pelvis. The knees should also be unlocked. It is also important to avoid prolonged static positioning; rotate retraction tasks if possible and use larger muscle groups for the same. It is best to use self-retaining retractors when available.

If using foot pedals for cautery or other energy devices, they should be positioned so that they can be reached without balancing on one foot. Ideally, they should be placed next to the foot and positioned toward the target quadrant. Neutral posture can be enhanced by keeping neck flexion <30 degrees and twisting <15 degrees, keeping the shoulders relaxed with abduction <30 degrees. The forearms should be positioned parallel to the floor with the elbows between 90 and 120 degrees flexion. Lastly, the wrists are best kept in neutral posture by keeping extension <20 degrees, flexion <40 degrees, radial deviation <15 degrees, and ulnar deviation <25 degrees. Surgeons should also consider sitting for portions of the case, if possible because standing is associated with higher levels of pain.[23] Setup and posture recommendations for open surgery are summarized in Fig. 17.1.[24]

Surgeons should also have awareness regarding the use of instruments such as clamps and needle-drivers and use ratchets where available to reduce hand fatigue. It is important that the



Positioning: Open Surgery
Maintain Neutral Neck Posture
select light headlamp
and high declination loupes
Engage Deep Trunk/Pelvis Muscles
maintain neutral torso posture
Avoid Pelvic Girdle Asymmetry
keep feet at hip widh apart
with weight evenly distribute
Able to Reach Pedals
without balancing
on one foot

reduce foot discomfort
and pain
Tuck Patient Arms
to avoid trunk twisting
Table Height
adjust to 70%–80% of elbow
height of tallest person, with
steps for others

FIGURE 17.1 Best practices for positioning in open surgery.

fingers fit comfortably in the instrument; otherwise, switching to a power grip (palming the instrument) can be useful to reduce finger fatigue.[19]

Surgical Ergonomics and Laparoscopic Surgery

As the field of surgery remains a physically and mentally demanding profession, introduction of minimally invasive approaches has added to the burden of physical workload. Laparoscopic surgery has become a mainstay in the proficient surgeon's toolbox. Although laparoscopy affords many benefits to the patient, including decreased length of stay, smaller incisions, and early return to work, it does put the surgeon and operating room staff at an ergonomic disadvantage. This is the result of several factors: awkward posture, static muscle load, eye strain, and mental stress. Regarding awkward posture, given the nature of longer instruments relative to open surgery, surgeons often position themselves away from the patient, introducing an overextension of their lumbar spine to manipulate instruments through trocars that are at a fixed access point beyond their natural reach. The transition from open to laparoscopic surgery results in a decrease in degrees of freedom (from 36 to 4).[25] This results in static, forced, and awkward long-term postures.[26] Additionally, during laparoscopic surgery, the height of the operating room table may result in excessive bending or stretching of the neck, back, and arms. Laparoscopic surgical instruments pose an additional risk to the ergonomics of a surgeon during the case. The ring handles common to many laparoscopic instruments cause flexion and ulnar deviation of the wrist. They may also result in inappropriate angles and lengths for the anatomy unique to each surgeon's hands and the tasks that need to be performed.[25–27] Specifically, the lack of an ergonomically designed handle that has not been adapted to the shape and size of every surgeon's hand that may use the tool can lead to discomfort and paresthesia of the digital nerves in addition to muscle fatigue.[26]

Furthermore, the operating room setup and the location of the monitors associated with laparoscopic procedures often prove to be ergonomically disadvantageous. The position of the primary screen may be positioned too far, too close, too low, or too high, causing excessive eye strain and additional neck and torso strain as a result of twisting, flexion, or extension. Many operating room configurations include the use of a primary and a secondary monitor, both often mounted from the ground, as opposed to mounted from a boom off the ceiling. These floor-positioned monitors can be difficult to maneuver around other pseudofixed structures in the operating room, resulting in an inconvenient placement of the monitors beyond an arm's length from the surgeon, resulting in eye strain. Finally, foot pedals can cause significant hindrances to ergonomics because of their placement too far away from the surgeon, too close to the surgeon, or too indistinct to the surgeon, which can cause muscle fatigue and cramps in the lower limb. Additionally, foot pedals can often impede a surgeon's balance during the case, which can cause more than just lower limb fatigue but may also have repercussions on the core.

When considering the ideal position for team members during laparoscopy, one must pay attention to avoiding awkward and static positions for long periods.[24] Specifically, it is important to pay close attention to minimizing the total amount of time the team members have shifted from their center of gravity. Although laparoscopy affords an upright trunk posture, it is essential to create an environment around the team that leverages this advantage. Specifically, the monitor on which intracorporeal images are being displayed should be positioned in a manner that places the top of the screen at eye level, with the optimal distance being about an arm's length. This is often best facilitated by having monitors projected from booms off of the ceiling because it is more feasible to place them at an arm's length from the surgeon and other team members. It is even better facilitated by having at least two, but often three, monitors available in the room.

When considering surgeon position during the procedure, the surgeon or assistant should have their shoulders relaxed and abducted <30 degrees. The upper arm should be positioned perpendicular to the floor. The neck should be in <20 degrees flexion with a tilt no greater than 15 degrees. The forearm and the elbow should be positioned such that they are between 90 and 120 degrees, and the forearm and wrists should be in a neutral position. Monitors should be placed with the top of the screen at eye level of the surgeon, with an optimal distance of an arm's length from the surgeon. This may need to be adjusted slightly depending on the monitor's size and resolution. The table height should be positioned between 70% and 80% of the height at which the elbows are positioned. A good approximation of this is usually at the level of the surgeon's pubic symphysis This configuration allows for the surgeon to not be bent over the patient, for the neck to be in a neutral position, and for the shoulders to remain relaxed throughout the operation.[28] Finally, when considering laparoscopic instruments, there should ideally be about 60 degrees between instruments to obtain the optimal working angle. This is best depicted in Fig. 17.2.[24]

Although the operating table height and monitor placement in conjunction with operator position are integral in minimizing the physical demand experienced during laparoscopy, a final attention to port placement in relation to the target anatomy is essential in creating an ergonomically optimized environment. The choice of port placement and the length of laparoscopic instruments can significantly affect the surgeon's efficiency and hence duration of the operation and may influence the degree of MSK strain experienced by the surgeon. Frede et al. noted that the ideal angle between laparoscopic suturing instruments was between 25 and 45 degrees in their in vitro models simulating intestinal anastomosis. Additionally, the instruments should be held <55 degrees above the horizontal. The ideal position of trocars involved an arrangement akin to an isosceles triangle. When working space is limited and trocars are placed <4 cm from each other, placement of the camera lateral to the working space can facilitate improved ergonomics and successful completion of tasks.[29]

Similar to open surgery, foot pedals should be placed directly in front of the working foot and in such a manner that surgeons do not need to balance on the opposite foot to reach and use the pedal during the course of the procedure.

Laparoscopic procedures in bariatric patients have special considerations because of the fact that they are more ergonomically challenging. This was demonstrated by a recent study done by Hilt et al. evaluating five surgeons performing bariatric procedures via laparoscopy and robotic assistance. The Rapid Entire Body Assessment (REBA) score takes into account six body parts: the neck, trunk, leg, upper arm, lower arm, and wrist in addition to activity, force/load score, and coupling. A score of 1 implies negligible risk with no action required, a score of 2 to 3 is low risk and change may be needed, and a score of 4 to 7 is medium risk that indicates further investigation is needed. A high-risk score is between 8 and 10 and implies that a change is needed. A score of 11 and above is a high-risk score with implementation needed. The median total REBA score was higher in laparoscopic procedures compared with robotic procedures (6 vs. 3).[30]

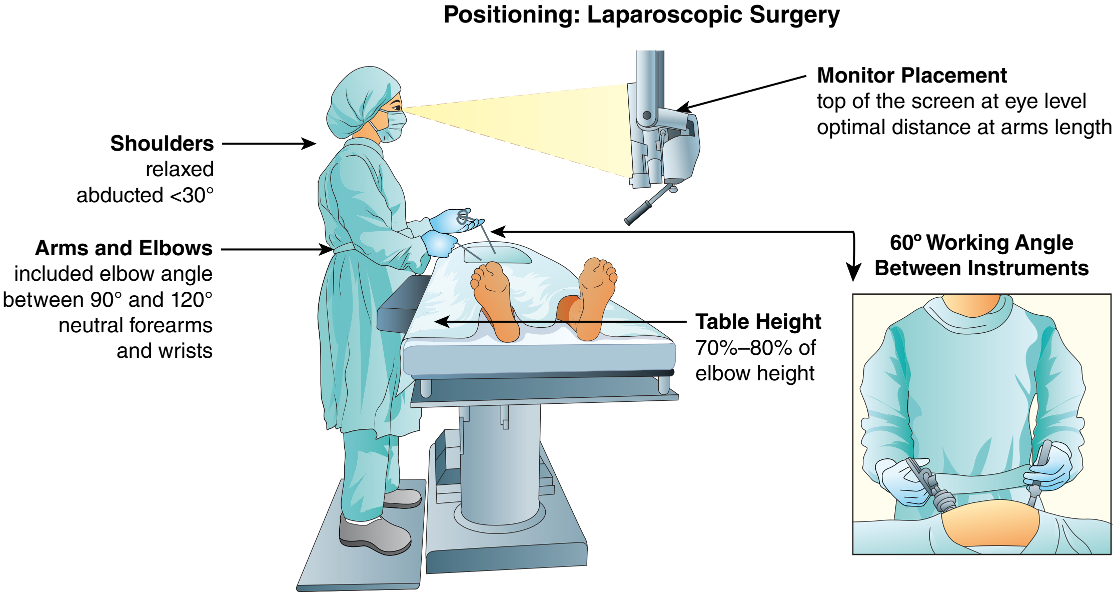

FIGURE 17.2 Best practices for positioning in laparoscopic surgery.

For laparoscopic procedures in bariatric patients, the operating room table should be lowered to approximately 1.25 to 38 cm below elbow level, depending on the patient's size, to account for increased effort and increased surface height from the patient's body habitus.[24] Additionally, the use of longer laparoscopic instruments in this interface requires a change in table height to afford the extra length.

Surgical Ergonomics and Robotic-Assisted Surgery

As minimally invasive surgery continues to evolve, RAS has been increasingly used in a broad range of common surgical procedures.[31] Although the transition from open to laparoscopic surgery decreased the degrees of freedom that a surgeon has (36 vs. 4),[26,27] RAS has returned dexterity to minimally invasive surgery, with 7 degrees of freedom with the added benefit of a reduction in hand tremor.[25,32–35] The landscape for RAS is expanding; however, the current market rests in a surgeon console remote from the bedside model. The surgeon console is approached in a seated position with the surgical field projected through a viewfinder, along with hand and foot controls that operate the surgical instruments at the bedside.[34,36] RAS has been touted as the solution to our ergonomic needs related to both laparoscopy and open surgery. Specifically, compared with laparoscopy, RAS touts an improvement in visualization, posture, and manipulation. In regard to visualization, the three-dimensional view of the surgical field with depth perception is unlike conventional laparoscopic views that remain two dimensional. The surgeon's three-dimensional view is positioned in the remote console in line with the viewfinder, which allows for an ergonomic advantage. The view is in the line of sight of the surgeon's eyes, and the surgeon can improve magnification and focus of the image at the console. This assists in overall reduction of neck strain and eye fatigue. Postural advantages are offered by a seated position and the liberation of not being constrained by the sterile surgical field. Finally, the benefits of robotics in manipulation are encompassed by the 7 degrees of freedom, use of articulated instruments, ability to scale movement, cancellation of tremor, and elimination of the fulcrum effect.[34–36]

However, RAS has its own ergonomic challenges. Some studies have demonstrated that the fixed position of the console binocular viewer could produce an inadequate spinal posture with resultant MSK disorders.[37] Additionally, the lack of an ergonomic seat can contribute to these disorders as well.[37] Stewart et al. noted that surgeons <66 inches in height (short surgeons) reported significantly more pain compared with their taller counterparts after both open and robotic operations; however, they had less physical demand when using the robotic system.[38] Conversely, Plerhoples et al. found that taller surgeons were more likely to attribute their pain to robotic surgery ($p = 0.04$). The most cited body parts requiring treatment for those experiencing pain attributed to robotic surgery include the neck, lower back, and the upper back.[39] Others have also noted that there can be significant eye strain and finger pain after repeated use of RAS.[24]

Optimizing ergonomics in RAS is best summarized in Fig. 17.3A. Essential to optimizing ergonomics in the robotic console is the selection of an appropriate chair. A seat with lumbar support, adjustable height, and lockable wheels is imperative. Adjustment of the chair should occur to optimize the seat of the chair at the level of the popliteal fossa, with the thigh parallel to the floor. The knee in this position is bent at approximately 90 degrees. The feet should rest on the floor in front of the pedals at an angle of at least 90 degrees, with dorsiflexion of the foot limited to no more than 25 degrees when controlling the foot switch. The arms should rest on the armrest with relaxed shoulders. The arms should be placed close to the trunk with the elbow angle between 90 and 120 degrees. The back should have <15 degrees of flexion. The viewfinder should be placed so that the eyes are in line and are deviated no more than 30 degrees from the horizontal. The key to maintaining optimal ergonomics during the procedure is to use the clutch mechanism often—otherwise known as *Always Be Clutching*, or ABC—in order to maintain the hands and wrist in a neutral sweet spot. It is best to keep the hand controls from drifting deep into the console or high in the console near the headrest and avoid awkward postures demonstrated in Fig. 17.3B.[24]

Surgical Ergonomics and Endovascular Procedures

The field of vascular surgery has evolved rapidly in the last decade, with the chief advancement being the development of catheter-based

technologies and advanced imaging techniques. These innovations have led to a significant shift from open to minimally invasive (and hybrid procedures). These approaches allow vascular surgeons to perform increasingly complex procedures, which lead to improved patient outcomes with shortened recovery times. However, these advances come at a cost.

Survey-based data from the Society of Vascular Surgery demonstrate that 52.7% of respondents were worried that physical discomfort would affect career longevity. Both open and endovascular surgeries are associated with pain; however, >65% of vascular surgeons are in a moderate amount of pain (≥4 on a Borg 0–10 pain scale) at the end of a full operating day performing open surgeries.[15] The percentage of surgeons reporting moderate pain was lower for endovascular procedures (about 54% and 19% for endoarterial and endovenous procedures, respectively). Other risk factors for moderate to severe pain included long case time (measured by percentage of cases over 3 hours) for open and endovascular arterial surgery and surgeon BMI for endovascular surgery (possibly because of the need for lead aprons, leading to added weight). The location of pain also varies by surgical approach, with open procedures having high rates of neck and lower back pain in contrast to endovascular procedures, which are more likely to lead to lower back issues, followed by the neck and upper back. This is likely related to less strain on the neck with endovascular procedures, with surgeons looking ahead at a screen rather than flexing their neck and back forward during an open case. This is also borne out by objective studies using posture recording devices in that neck flexion angles were worse for open cases compared with endovascular cases (a mean of 42 degrees compared with 24 degrees), although both are still quite high.[13]

To optimize positioning for open vascular cases, it is important to set up the table and equipment appropriately, as outlined in earlier sections. For endovascular cases, monitors should be placed with the top of the screen at eye level of the surgeon, with an optimal distance of an arm's length from the surgeon (similar to laparoscopic surgery) so as to reduce neck strain. The table height should be positioned between 70% and 80% of the height at which the elbows are positioned and should be adjusted as needed during hybrid cases. When performing fluoroscopy, foot dorsiflexion should be limited to <25 degrees, and alternating feet throughout the case can help reduce the strain from uneven weight distribution.[40]

Lead aprons are a significant source of ergonomic stress for interventional radiologists, interventional cardiologists, orthopedic surgeons, and now, vascular surgeons doing endovascular procedures.[41] A lead apron weighing 15 pounds has been reported to exert almost 300 pounds per square inch of pressure on the intervertebral disk space.[42] Best practices when using aprons are to use two-piece models rather than single-piece ones to distribute the weight between the shoulders and hips and using custom-fitted ones if they do not fit well. Lumbar support belts can also decrease lower back strain. Surgeons can also use lead composite or nonlead options for radiation protection. The latter are made with metals such as antimony and tungsten and often weigh 40% to 50% less than lead aprons, while providing equivalent radiation protection for the scattered radiation exposure in clinical settings.[43]

Surgical Ergonomics and Gastrointestinal Endoscopy

Endoscopic gastroenterology proceduralists are not immune from MSK disease, with survey studies reporting a prevalence of endoscopy-related injuries (ERIs) ranging from 39% to 89%. Similar to surgical procedures, the major contributors to these injuries include repetitive and high-force loads in nonneutral postures. Endoscopic maneuvers leading to disproportionate loads include use of torque steering, grasping and stabilizing the endoscope controller, and manipulating the endoscope dial. Risk factors for ERIs include higher procedure volume, time spent performing endoscopy, cumulative time in practice, small hand size, age, and female sex.

Similar to laparoscopy, optimal setup for endoscopy involves placing the monitor directly in front of the operator just below eye level, with the viewing angle between 15 and 25 degrees below horizontal. Shergill et al. recommended that monitors be adjustable from 93 to 162 cm above the floor in order to accommodate the majority of endoscopists (5th percentile female height to 95th percentile male height).[44] They also estimated that the optimal viewing distance of video monitors during endoscopy is between 52 and 182 cm, depending on monitor size, image clarity, and endoscopist's preference. With respect to gurney or table height, it should be adjusted to allow holding of the endoscope between elbow height and 10 cm below elbow height to minimize forward flexion of the back and shoulder abduction.

There are data showing that ERIs are more common in small-handed proceduralists.[45] Having reusable dial adapters that can be clipped to the standard right/left angulation control knob may allow users with smaller hands to manipulate the dials more easily. Therefore, the American Society for Gastrointestinal Endoscopy guidelines recommend that these adjuncts be made available in endoscopy suites for small-handed endoscopists to use as needed.[45]

ADDITIONAL INTRAOPERATIVE CONSIDERATIONS

Optimal Use of Adjuncts

As indicated previously, using adjuncts such as surgical loupes and headlamps significantly increases neck strain. Added weight from lead glasses used during interventional procedures can also contribute to this. General considerations for using these adjuncts are to use the most lightweight models and only for short durations during critical steps of the procedure, so as to reduce the load on the spine. When selecting loupes, it is important that they are well-fitting and have the desired angle of declination. In general, a steeper angle of declination will reduce forward flexion of the neck and hence reduce neck strain. A recent intervention study has demonstrated that best practice for a loupes fitting session involves not only consideration of the type of work (e.g., perineal work requires a smaller angle of declination) but is also facilitated by re-creating the work environment and using the expertise of surgeons, senior trainees, and ergonomists.[46] Rather than headlights, surgeons can consider using lighted retractors to reduce the added weight of these adjuncts on the spinal column. Drop-away radiation protection aprons can be removed easily while remaining in the sterile field and therefore might be helpful to reduce ergonomic strain.

Antifatigue Mats and Footwear

Antifatigue mats are recommended by the Occupational Safety and Health Administration for workers standing for long hours,[47] including hospital spaces such as labs. The rationale is that they decrease fatigue by causing minor postural instability, thereby increasing subtle movements of the legs and increased blood flow to reduce injuries in the legs and feet. However, there has been resistance to their use in the operating room because of infection control concerns. Antifatigue mats have demonstrated benefit in the postoperative discomfort and fatigue experienced by surgeons.[48] Floor mats would need to be easily and regularly cleaned; otherwise, they represent a potential biohazard. Alternatively, disposable or autoclavable options may be used. They are also a potential tripping hazard and should have beveled edges to minimize the risk of falls. Overall, the potential benefits and relative low cost outweigh any potential risks, and surgeons should consider using them for all types of procedures, open or endoscopic. Surgeons should also invest in support stockings or socks and supportive footwear that provides some cushioning from the floors of procedure suites, especially when they are not constructed of materials to provide the same.

APPROACH TO PREVENTION OF INJURY

In addition to the strategies optimizing the operative work area during open, laparoscopic, and robotic procedures, further strategies can be employed to effectively prevent fatigue and injuries for the team. Intraoperative breaks to allow for recalibration of both mind and body can assist in avoiding injury. A great tool for intraoperative breaks is the Mayo Clinic OR Stretch tool that comes in the form of a mobile device application with associated instructional videos on YouTube. The information also comes in a bundled PDF format for use and placement in and around the operating room. The intraoperative stretch break lasts approximately 70 seconds, and a guided tool is found on the OR Stretch website or in the mobile-based application.[49] Hallbeck et al. found that the inclusion of intraoperative microbreaks did not increase the operative time significantly. They also found that during intraoperative microbreaks there was no significant impact to workflow with or attention caused by the intervention.[50] There is also a set of between-surgery stretches that can be performed before and after operations. The video guides assist surgical staff through a short series of stretches, which aim to counteract the effects of intraoperative strains on the surgeon's positions and posture.[49]

Maintaining wellness outside of the operating room facilitates prevention of injuries in the operating room. In addition to the overall benefits of exercise to cardiovascular health, physical fitness and exercise can optimize ergonomics in the operating room. Particularly, exercises that focus on core and back strength, flexibility, and overall posture can assist in prevention of injuries. Performing these activities for only 15 to 30 minutes four to five times a week can provide enormous risk reward.[51] Using stretching, yoga, strength training, and Pilates in any combination is essential to maintaining flexibility and core and back health. An example of exercises include latissimus pull-downs, narrow-grip or bent-over dumbbell rows, and rowing machines, which focus on strengthening the back, as well as medicine ball rotating crunches, Russian decline twists, and hanging leg raise twists, which focus on core strength.[51] Giagio et al. demonstrated that a preventive program including nonresistance active exercises and static stretching before and after surgeries reduces surgeons' back pain and analgesic use.[52] The ACS Ergonomics Taskforce recommendations document is also an additional resource for intraoperative and between-surgery stretches.[19]

Office Ergonomics

Because surgeons spend a significant amount of time charting in the electronic medical record (EMR), office ergonomics also need to be optimized. Institutions often have resources, including certified ergonomists, to help in the appropriate setup of office spaces. As with ergonomics in the operating room, table height and computer monitor distance are important. It is recommended that surgeons use a comfortable chair with adjustable seat height, lumbar support, and lockable wheels. Postural awareness is also important, and individuals should sit back in the chair with shoulders and hips aligned, knees bent at 90 degrees to the upper thigh, and feet on the floor (or footrest for shorter individuals). The keyboard should be easily accessed while keeping the wrists straight. The monitor is best positioned at or just below eye level at a viewing distance of 19 to 24 inches to keep neck flexion to a minimum. The user's eyes should look slightly downward when viewing the middle of the screen.[53] The use of laptops is discouraged, but if absolutely necessary, use of a laptop riser and an external keyboard and mouse is advised.

Surgical Culture and Organizational Responsibilities

The best strategies for changing the status quo can be derailed by the culture of the profession and our workplaces. Surgeons and surgical trainees rarely report their work-related MSK symptoms and injuries, partly because of the stigma associated with being "less than" and for fear of losing their careers. This is similar to the barriers around reporting of surgeon mental health issues and can disproportionately affect individuals who do not fit the mold of the "typical surgeon." It is therefore paramount that there be well-established and supportive reporting mechanisms for injuries both within departments of surgery and institutional perioperative services. This will allow for early referrals to physical therapy, occupational health, and others for evaluation and appropriate treatment. Early intervention is needed to prevent injuries from becoming chronic.

Surgical ergonomics needs to be an integral part of surgical training. To this end, several studies have demonstrated that instituting an ergonomics curriculum for residents is both essential and feasible.[7,8,54] The newly formed Society of Surgical Ergonomics is also committed to improving the status quo via its website and annual research symposia.

SUMMARY

Work-related MSK injuries are common in surgeons and are a significant source of disability and burnout. Awareness and education regarding measures to improve ergonomics for surgeons are lacking. Optimizing positioning of equipment and personnel, postural resets, taking breaks, and stretching are all tactics to improve the ergonomics and physical health of practitioners, both within and outside the operating room.

Systematic review and meta-analysis of the prevalence and prevention of work-related musculoskeletal disorders (MSDs) among at-risk physicians, such as surgeons and medical interventionalists. The main findings describe a high prevalence of MSDs, increasing evidence of them over time, and that 12% of at-risk physicians with MSDs require a leave of absence, practice restriction or modification, or

early retirement. It also highlights the lack of awareness and prevention.

Lowndes BR, Forsyth KL, Blocker RC, et al. NASA-TLX assessment of surgeon workload variation across specialties. *Ann Surg*. 2020;271(4):686-692.

This study evaluates measuring and improving surgeon workload and performance in operating rooms. The authors used a modified NASA Task Load Index survey to assess workload across different surgical specialties and identify factors that affect difficulty and performance. They found that mental, physical, and effort demand were the highest-rated workload subscales and that unexpected difficulty had negative implications for performance and procedural duration. They suggested re-engineering the surgical planning process and procedural environment to optimize workload and performance for improved surgical care.

This is a high-yield video of operating room stretches to perform between surgeries as a tool for prevention of workplace injuries. The stretches aim to counteract the effects of intraoperative strains of the surgeon's positions and posture and are performed without breaking scrub.

Stewart C, Raoof M, Fong Y, Dellinger T, Warner S. Who is hurting? A prospective study of surgeon ergonomics. *Surg Endosc*. 2022;36(1):292-299.

This study investigates how surgeon height and sex affect ergonomic outcomes during open and robotic surgery. The authors hypothesize that robotic surgery would reduce pain and workload for surgeons, especially for short and male surgeons, who may experience more ergonomic challenges during open surgery. They collected data from 20 surgeons to compare pain scores and task load between open and robotic surgery. The paper finds that short and male surgeons report significantly more pain after both open and robotic surgery but have less physical demand when using the robotic system, suggesting that robotic surgery may offer ergonomic benefits for these groups.

Tetteh E, Wang T, Kim JY, et al. Optimizing ergonomics during open, laparoscopic, and robotic-assisted surgery: a review of surgical ergonomics literature and development of educational illustrations. *Am J Surg*. 2024;235:11551.

This reference is a narrative review of the current literature on surgical ergonomics. The authors reviewed the literature on ergonomic recommendations for open, laparoscopic, and robot-assisted surgeries and created best practice illustrations for each modality. The pictorial reminders can be used to develop ergonomic education materials and reduce ergonomic risks in the operating room and can be used with resident education.

CHAPTER 18

Surgeon Health and Well-Being

Carrie Cunningham, Tasha Hughes, Jeffrey M. Smith, and Taylor S. Riall

OUTLINE

Introduction
- Defining the Challenges

Reciprocal Domains of Physician Well-Being
- Personal Resilience
- Developing Resilience
- Executive Coaching

Shifting of Priorities and Major Life Stressors
- Burnout and Consequences
- Mental Health Support
- Culture of Wellness
- Leave Policies (Maternity, Paternity, Health)
- Pregnancy-Related Challenges in Surgery
- Leave Policies and Tenure-Clock Stops
- Second Victim Programs
- Efficiency of Practice
- Addressing Challenges in Modern Healthcare Delivery to Promote Physician Health and Well-Being
- Functional Teams and Team Models of Care
- Intradisciplinary Collaborative Team-Based Models
- Large Group Practices
- Interdisciplinary Teamwork
- Advanced Practice Professionals
- Optimizing Use of the Electronic Medical Record
- Scribes and Medical Assistants/Support Staff

Conclusions

INTRODUCTION

Defining the Challenges

Surgery is a purpose-driven career requiring tremendous investment of time, money, energy, and fortitude. Medical education and surgical training occur during years that might otherwise be spent developing personal and social networks, including relationship building and starting a family. Once into practice, surgeons commit significant time to stay up to date on the latest surgical techniques and research to maintain current best practices in improving the health and well-being of patients. Frequently, however, this commitment of time and energy may come at the cost of other valuable pursuits.

Surgeons often neglect their physical and mental well-being to prioritize professional responsibilities. Consider the following scenarios. Your colleague is out sick, and the service needs to be covered, so you rearrange your schedule to support the service. An insurance company denies an MRI in a patient who needs it, and an MD appeal is required, so you push out your dentist appointment to wait on hold to complete the appeal. You are called urgently to help a colleague in the operating room when you are out to dinner with your family. You excuse yourself, leaving your family to finish dinner without you. At some level, we all went into medicine to help patients, and, in almost all instances, we do the best thing for the patient, even if it comes at a significant personal cost. A recent opinion piece in the *New York Times* suggests that the business of healthcare may exploit this central ethos adopted by nurses and physicians.[1]

The demands placed on physicians and other medical professionals are real, often requiring commensurate growth in time and resources. For all healthcare workers, administrative burdens, including the electronic medical record (EMR), insurance companies, and regulatory issues, continue to expand and take time away from what we are trained to do. For surgeons, the immediacy and acuity of patient care are often high. Patients are undergoing complex procedures with multiple underlying comorbidities. In the past, patients would stay in the hospital for days after a cholecystectomy or colon resection. Enhanced recovery pathways set a standard for little or no inpatient admission and often around-the-clock outpatient management, placing even greater pressure that outcomes and quality of care must be pristine and nearly flawless. Surgical technology is rapidly changing, and surgeons must learn and adopt new technology, or their relevance may be challenged. Likewise, new medications that directly affect surgical care are released on the market regularly. Without conscientious effort to stay up to date, surgeons and their surgical care will quickly fall behind the standard of care.

This chapter aims to help surgeons recognize risks to their health and introduce potential strategies that promote sustainable surgical careers and improved health of the surgical workforce. Traditional surgical training teaches us that failures are a product of individual shortcomings, including not working hard enough, not caring enough, or not being smart enough. At the same time, surgical culture rewards, and even idolizes, members of the workforce who demonstrate workaholic or perfectionist behaviors as martyrs and superheroes. This combination of individual traits and surgical culture leads to a set of expectations for ourselves and each other that are often unattainable. This chapter seeks to reframe the interaction between practicing surgery and maintaining healthy mental and physical habits. Although there are many rewarding aspects of a surgical career, we all experience periods when we feel physically, mentally, and emotionally drained from the rigorous demands. To continue to provide outstanding, high-quality care, surgeons themselves must be healthy (physically, mentally, and emotionally), and we must, as a community, work to support all our members' health.

In this chapter, we will define relevant terminology for the mental and physical health of surgeons, describe the scope of the problem, and propose both individual and systems-based approaches to improve the health and well-being of the surgical workforce.

Defining Terminology

Significant heterogeneity exists in the terms describing the healthcare workforce's physical, mental, and emotional health. The following definitions are not exhaustive, but they frame how we will use these terms throughout the discussion. The terminology we use matters to communicate clearly and honestly about the challenges and potential solutions. Burnout and wellness are not antonyms, and strong wellness habits and personal resilience are insufficient to overcome toxic environments and, thus, will not ensure health and well-being.

Wellness and Well-Being

Wellness is often confused with health, well-being, and happiness (Fig. 18.1). Although there are common elements among them, *wellness* is associated with being aware of and making choices that lead to optimal holistic health and well-being.[2] *Well-being* refers to optimal mental, emotional, and social health and functioning, including a person's overall satisfaction with life, sense of purpose and fulfillment, and ability to cope with stress. Well-being is influenced by various factors, including personal characteristics, social relationships, socioeconomic status, and environmental factors, and it varies across individuals and cultures.

Burnout

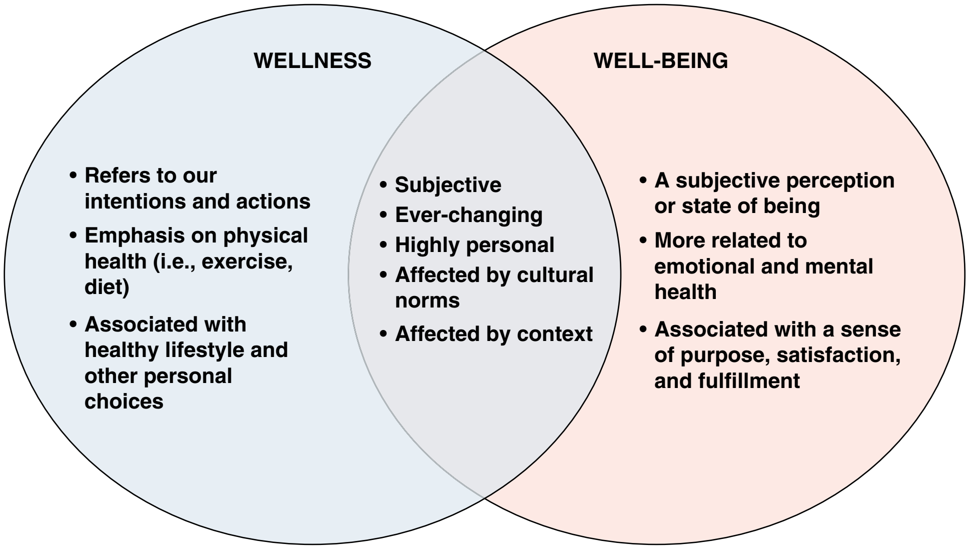
Burnout in medicine has become increasingly recognized over the past two decades. The World Health Organization (WHO) describes burnout as a "psychological syndrome emerging as a prolonged response to chronic interpersonal stressors at work." The syndrome is defined across three dimensions: overwhelming exhaustion (emotional exhaustion), feelings of cynicism and detachment from the job (depersonalization), and a sense of ineffectiveness and lack of personal accomplishment (decreased sense of personal effectiveness).[3] Burnout may be considered analogous to developing a stress fracture. Stress fractures are caused by repetitive stress to bones, leading to microfractures that occur at a pace that exceeds the ability of the bone to heal fully. Burnout is a state of sustained stress caused by factors in the healthcare system that inflict repetitive mental, emotional, and physical pressure on the mind and body without allowing proper time for rest and recovery. Physicians experiencing burnout cite too many bureaucratic tasks, lack of respect from colleagues, and too many hours at work as the three most significant contributors to burnout.[4] Although any of these alone is not the cause, the repetitive nature of the experiences over time chips away at the joy and fulfillment that may be better realized if these chronic stressors were mitigated.

Health

The WHO defines *health* as "a state of complete physical, mental, and social well-being and not merely the absence of disease or infirmity." Likewise, surgeon health and well-being are not simply the absence of burnout. It encompasses our physical health, our mental health, our emotional health, and our social support.

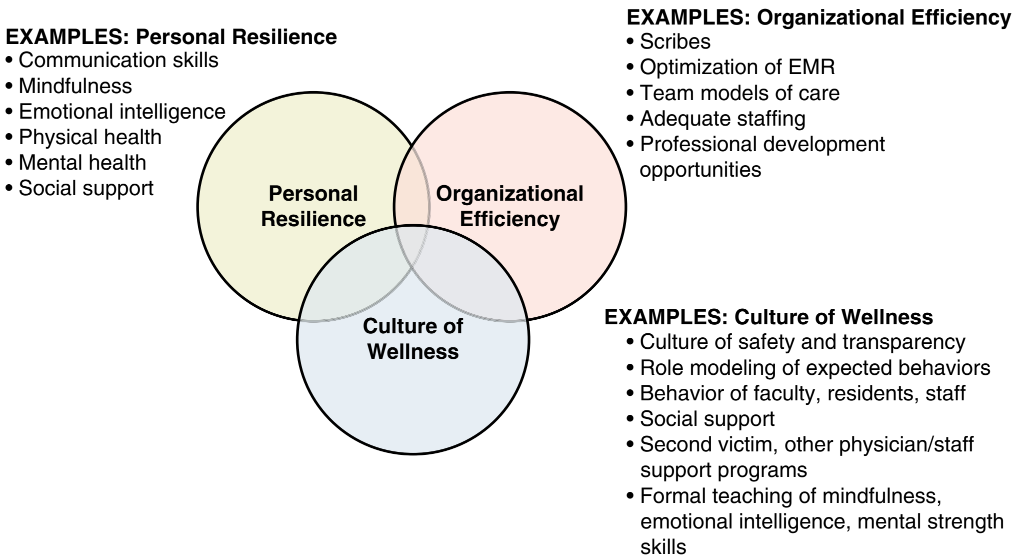
Resilience, Distress, and Moral Injury

Resilience is defined as the ability of a substance or object to spring back into shape or the capacity to withstand or recover quickly from difficulties. For healthcare professionals, resilience refers to one's ability to recover from harm, including illness (physical, mental, or emotional), moral injury, stress (chronic or acute), distress, and burnout.



WELLNESS
WELL-BEING
• Refers to our intentions and actions
• Emphasis on physical health (i.e., exercise, diet)
• Associated with healthy lifestyle and other personal choices
• Subjective
• Ever-changing
• Highly personal
• Affected by cultural norms
• Affected by context
• A subjective perception or state of being
• More related to emotional and mental health
• Associated with a sense of purpose, satisfaction, and fulfillment

FIGURE 18.1 Distinct and overlapping domains of wellness and well-being.



EXAMPLES: Personal Resilience
• Communication skills
• Mindfulness
• Emotional intelligence
• Physical health
• Mental health
• Social support
EXAMPLES: Organizational Efficiency
• Scribes
• Optimization of EMR
• Team models of care
• Adequate staffing
• Professional development opportunities
Personal Resilience
Organizational Efficiency
Culture of Wellness
EXAMPLES: Culture of Wellness
• Culture of safety and transparency
• Role modeling of expected behaviors
• Behavior of faculty, residents, staff
• Social support
• Second victim, other physician/staff support programs
• Formal teaching of mindfulness, emotional intelligence, mental strength skills

FIGURE 18.2 Reciprocal domains of physician well-being. *EMR,* Electronic medical record.

Although stress can be positive and motivating, distress is the flip side of the coin. Distress may lead to feelings of being overwhelmed and increased symptoms of burnout. Physician distress can be brought on by work or personal stressors, such as severe or unanticipated adverse outcomes, lawsuits, bullying, sexual harassment, moral injury, or physical and mental illness. *Distress* can also be brought on by *chronic stress* that is either unrecognized, suppressed, or addressed in unhealthy ways.

For some surgeons, burnout does not resonate with the sense of identity. It suggests a failure of resourcefulness and resilience, traits that most of us value and have finely honed through decades of intense training and demanding work. Physicians, by nature, *are* resilient. Moral injury was first described based on the experiences of soldiers at war and represented "perpetrating, failing to prevent, bearing witness to, or learning about acts that transgress deeply held moral beliefs and expectations."[5] Moral injury may develop and accumulate when threats from administrative burdens, adverse patient outcomes, medicolegal challenges, or interprofessional conflict are present in one's professional sphere.

RECIPROCAL DOMAINS OF PHYSICIAN WELL-BEING

Physician well-being has been described as encompassing three reciprocal domains: (1) personal resilience, (2) culture of wellness, and (3) organizational efficiency of practice (Fig. 18.2).[6] These domains are inherently interconnected, and changes in one domain may result in both intended and unintended changes in the others. Additionally, addressing a single domain in isolation from the others is unlikely to improve physician well-being significantly. As such, organizational and physician engagement are necessary to support and improve the surgical workforce's health and well-being. A comprehensive list of factors is listed in Table 18.1.

TABLE 18.1 Individual and Organizational Factors That Affect Surgeon Health and Well-Being

INDIVIDUAL FACTORS	ORGANIZATIONAL FACTORS
Personal Factors	**Culture (Departmental or Institutional)**
Physical health	Collaborative work environment
Acute illness	Psychological safety
Injury	Culture of safety
Chronic illness	Autonomy
Relationships	Learning environment
Social support	Support resources for acute events
Financial pressure	Clear expectations
	Policies (leave policies, tenure-clock stop)
	Mentorship
Healthcare Role/Practice	**Organizational Factors**
Private practice (large or small group)	Appropriate staffing and team redundancy
Academic practice	Human resource policies
Patient population/severity of illness	Compensation
Call burden	Bureaucracy
Team support	
Trust in partners	
Sense of purpose	
Personal Skills	**Regulatory**
Emotional intelligence	Accreditation programs (i.e., Commission on Cancer, National Accreditation Program for Breast Cancer)
Social awareness	High-risk assessments (The Joint Commission)
Relationship skills	Publicly reported quality ratings
Communication skills	
Organizational skills/efficiency	
Coping skills	
Mental strength skills	
Personality traits	

Personal Resilience

Physical Health for Surgeons

Surgeons are, in many ways, similar to high-performance athletes, with a specific and highly developed skill set. Our skills are honed over years of training and require continuous practice, discipline, and new skill acquisition to maintain and advance in our careers. Surgeons are goal oriented and often derive professional gratification from having a large effect on patients. Like many professional athletes, we are part of complex teams, and our performance and ability to interact with that team are essential to our success.

	Professional Athletes	Surgeons
Hours worked	4–5/day	10–15/day
Career span	7–10 years	30+ years

FIGURE 18.3 Daily and lifelong work demands of surgeons and professional athletes.

Despite these similarities, some aspects of surgical careers are unique and present specific challenges. Unlike a professional athlete who trains for 4 to 5 hours a day and has a career span of 7 to 10 years, surgeons work 10 to 15 hours a day and have a career span of 30+ years. The human capacity for work increases until age 30 and then declines throughout the subsequent years of adulthood (Fig. 18.3). For surgeons, this age corresponds with the completion of training. At this point, however, the physical and mental demands continue to escalate and are sustained over the length of a decades-long career. Therefore, taking care of one's body and mind is critical to continue to meet the mental and physical challenges of our field. Despite our ethos, surgeons are human. Surgeons should focus on three fundamental tenets: exercise, sleep, and nutrition. As in any high-performance discipline, we must fuel our bodies (and avoid toxins), train, rest, and recover.

Exercise is essential and should include flexibility, resistance, and aerobic conditioning. This does not need to be hours every day. Even 30 minutes three times a week or smaller amounts daily can make a big difference in physical and mental health. If nothing else, take the stairs or take a walking meeting. Many surgeons have an "all or nothing" mentality. Remember, some exercise is better than none. It is quality, not quantity, and many short workouts of varying intensity can provide significant value and fit into the short downtimes in busy workdays.

Strategic movement is another crucial component that surgeons should consider. We strongly recommend optimizing ergonomics and introducing movement into operating room routines. This can be hard to remember in the operating room because surgeons are focused on what they are doing. There is growing recognition of the benefit of microbreaks, whether to stretch, drink water, use the restroom, or clear your mind. Surgeons should routinely step away from the table, stand up straight, tighten their core muscles, stretch, flex their knees, or scrub out for a drink, snack, or bathroom break, as our anesthesia and nursing colleagues do. One organizational and cultural opportunity is to make these microbreaks a team effort and expectation for all members of the surgical care team. If led by the surgeon, this can become the norm. Set alarms for small breaks when working outside the operating room, either in the clinic or in other administrative or academic work. Turn a meeting into a walking meeting, go up and down the stairs a few times, use a stand-up desk, or sit on a balance ball.

Sleep deprivation and fatigue are significant challenges in the surgical workforce, particularly during the years of surgical training. Despite increasing knowledge about the importance of adequate sleep on short- and long-term health outcomes, workplace demands are ever-growing, and opportunities to recover from that demand are limited. This leads to chronic fatigue and reduced ability to perform at our best. Sleep deprivation and resulting fatigue have been shown to significantly negatively affect performance in medicine, including diminished cognitive capacity, reduced accuracy, increased medical errors, and decreased performance by up to 32% in terms of technical skill.[7] In fact, the influence of on-call–associated sleepiness on performance is equivalent to that of 0.04% to 0.05% blood alcohol concentration, which is roughly equal to having had two alcoholic drinks.[8]

Although systems have worked to limit overall work hours, frequency of 24-hour shifts, and changes in day-night cycles, some aspects of our profession require availability on a nearly constant basis. Acute and chronic sleep deprivation remains a problem. In many current workplaces, there is not an easy solution that affords all members of the surgical workforce this essential time for rest and recovery. Although difficult to accomplish from a practical and financial perspective, the solution is adequately staffed, functional teams that allow for safe and culturally accepted cross-coverage. This requires trust between healthcare workers at all levels of the organization, high-quality communication, and well-defined clinical management protocols.

The definitions of adequate nutrition may vary by individuals and between cultures. However, many surgeons may go long periods without eating or drinking water, resulting in decreased acuity, mood disruption, development of kidney stones from dehydration, or binge eating behaviors. Although there is no one-size-fits-all approach to nutrition in a busy surgical career, taking time to fuel one's body regularly, either with nutritious snacks or well-timed breaks for meals, should be both the responsibility of individuals and systems to support the adequate nutrition and hydration of healthcare workers in the operating room.

Developing Resilience

Stress is inherent in surgical training and careers, and surgical training should include formal teaching of skills for managing this stress. Although surgeons must be technically skilled, there is more to our profession than technical expertise. Cognitive but nontechnical skills, including mindfulness, self-awareness, emotional intelligence, emotional regulation, communication, conflict, management, and cultivation of relationships, are critical to effectively managing the ever-present stress in our environment. Given the complex, matrixed environments in which we work, these skills are, in fact, essential to success and longevity in a surgical career. These key competencies are entirely lacking or severely de-emphasized in the current training paradigm.

A surgeon's ability to master these nontechnical skills and respond to challenges unique to medicine and inherent in our day-to-day lives is at the core of their well-being. There are widespread systemic challenges and unique institutional and hospital-specific challenges in medicine, some of which may be beyond the control of an individual surgeon. The ability to respond to such challenges is both a consequence of and a contributor to well-being. A surgeon who is tired and hungry and has not had the time to recharge emotionally or psychologically may have more difficulty regulating their emotions and feel less in control of how they respond in a given circumstance. The ability to react effectively significantly affects their well-being and, potentially, the well-being of everyone in their sphere. Both optimizing the environment and teaching individual resilience are essential for well-being.

Formal Education/Training in Mental Skills

Tools such as mindfulness, meditation, and exercise can be taught and practiced. The development of these skills allows individuals to respond more effectively to stress. Mindfulness training involves the development of moment-to-moment awareness of thoughts, emotions, and sensations; emotional regulation (or nonreactivity in response to stimuli); and the ability to understand the perspective of oneself and others. The most well-studied form of mindfulness training is Mindfulness-Based Stress Reduction (MBSR), developed by Jon Kabat-Zinn in the 1980s. The formal MBSR curriculum is 8 weeks long and has been shown to decrease stress and burnout, protect executive function, and enhance performance in multiple high-stress populations. In other high-performance professions, including elite athletes, Marines, and police special forces, mindfulness-based interventions tailored to the target population have improved stress-coping skills, executive function, and performance.[9,10]

Several training programs across the country have focused on mental skills training. Broadly, mental skills encompass a set of psychological techniques, both somatic and cognitive, that help individuals and teams achieve optimal performance. Optimal performance is achieved through skilled management of stressors inherent to high-stakes endeavors, such as complicated or high-risk operative cases. These skills have been widely applied in sports psychology. The somatic domain focuses on mindfulness-based interventions to improve situational awareness and emotional regulation. The cognitive part includes mental imagery, mental rehearsal, goal setting, and performance routines.

At the University of California, San Francisco, a group developed the Enhanced Stress Resilience Training (ESRT) program. This curriculum was based on MBSR but tailored and optimized for surgeons' time constraints and academic schedules. The program has undergone several iterations, but the final modified program reduced the traditional 9 weeks to 5 weeks, shortened class duration from 2.5 hours to 1 hour, changed a 7-hour silent retreat to a 2- to 3-hour hike, and shortened daily practice from 45 minutes to consistent daily practice with a goal of 20 minutes daily (Table 18.2).[10,11]

The initial iteration was a pilot randomized controlled trial in 21 surgical postgraduate year 1 (PGY1) residents.[10] The program was feasible and acceptable. The primary outcome was perceived stress; secondary outcomes included change in executive function, burnout, depression, mindfulness, resilience, grit, motor skill performance, and changes in functional neuroimaging during an emotion regulation task. Measures were obtained at baseline (before the start of PGY1), postintervention (3.5 months after baseline), and at the end of PGY1 (12 months after baseline). The pilot study found increased mindfulness, lower perceived stress, improved working memory capacity, and improved technical skill times for ESRT participants compared with control arm participants. They noted a marked decrement in cognitive control and an increase in depressive symptoms among control participants.

The ESRT training was further adapted, and two small single-institution randomized controlled trials were performed (ESRT-1, $N = 44$ and ESRT-2, $N = 45$), with the latter including residents from nonsurgical specialties. Higher executive function and mindfulness scores were seen in ESRT-1, and lower emotional exhaustion and depersonalization scores in ESRT-2 compared with controls. There were no differences in perceived stress.[12]

Another group at Indiana University hypothesized that cognitive mental skills training would minimize performance deterioration in stressful operating room situations. They developed a mental skills curriculum that included (1) the science of attention, focus, and concentration; (2) goal setting; (3) activation management (skills to relax mentally and physically and techniques for raising energy when tired); (4) attention management (techniques for maintaining attention on the essential and stopping negative self-talk and redirecting attention from a distraction); (5) imagery; (6) refocusing strategies; and (7) preoperative mental routines.[11,13]

TABLE 18.2 Traditional Mindfulness-Based Stress Reduction (MBSR) Training and Enhanced Stress Reduction Training (ESRT) for Surgeons

ELEMENT	TRADITIONAL MBSR	ESRT (UCSF PROGRAM)	REASON FOR CHANGE
Total course duration	9 weeks	5 weeks	Minimize clinical disruption
Class duration (weekly)	2.5 hours	1 hour	Minimize clinical disruptions
Class format	Experiential, interactive, breaks, didactics	No breaks, video-based content	Enhance acceptability and accessibility
Retreat	8-hour silent sitting retreat at meditation center	3-hour hike	Request for group time and outdoor exposure; acceptability, feasibility
Assigned daily practice time	45 minutes daily	Consistent practice, with ideal 20 minutes daily	Surgeons failed at 20 minutes, and assignment added stress
Class content	1.5 hours meditation, 1 hour sharing stories/experiences	45 minutes meditation, 10–15 minutes explicit concepts	Preserve experiential learning but shorten time for feasibility and acceptability
Emphasis	Insight, lifelong learning about self	Develop resilience skill set, with specific practice and application	Address growing stress in surgical residency
Contextualization	Broad application of concepts	Techniques applied to specific scenarios in surgical environment	Explicit skills for stress management in common situations
Expectation	Committed formal practice	Train formally but "live your practice"	Capitalize on surgeons' ability for repetitive practice and ritual

UCSF, University of California, San Francisco.

Modified from Anton NE, Lebares CC, Karipidis T, Stefanidis D. Mastering stress: mental skills and emotional regulation for surgical performance and life. *J Surg Res*. 2021;263:A1-A12.

In this study, 46 residents underwent baseline testing, including a mental skills assessment and baseline performance of fundamental laparoscopic skills (FLS), including pattern cutting, peg transfer, and intracorporeal suturing. They were then randomized to mental skills training or control. Each group underwent eight training sessions over 3 to 4 months. For the control group, this was 45-minute FLS training with coaching provided by experienced laparoscopic surgeon trainers. Before FLS training, the intervention group received 45 minutes of mental skills training described earlier.

Participants were then tested doing a Nissen fundoplication in a live, anesthetized porcine model. The task was to place three intracorporeal sutures using their FLS. The first suture was placed under normal conditions. Then, the second and third were placed under stressful conditions. These conditions included a shorter-tailed suture, a camera offset in a side port, and a nurse interrupting performance with a mock page. The two groups had similar baseline technical performance. Under low-stress conditions, the two groups performed similarly on the posttest. The group who underwent the mental skills curriculum outperformed the control group under high-stress conditions, providing evidence that formal cognitive skills training can prevent performance deterioration under stressful conditions.[13]

Stanford University developed the Balance in Life Program in response to a resident suicide within the program. This program provides a formal curriculum to teach these noncognitive skills and provide residents and faculty with tools to improve their self-awareness, self-management, emotional regulation, relationship management, and individual resilience. In addition to formally training in these skills, this program and others like it demonstrate more holistic support to residents and faculty and create a culture supporting well-being. The program includes access to nutritional snacks in the hospital, team-building activities, group coaching sessions with a trained clinical psychologist for all residents, social support, and additional services for counseling, coaching, and mental health as needed for individual residents. This program is part of a larger focus on well-being at the departmental level but has yet to be formally studied regarding its effect on resident burnout, wellness, or satisfaction.

The University of Arizona implemented a resident well-being and resiliency program in 2016 based on the Energy Leadership model.[14] The model describes seven energy or awareness levels, providing a framework and language for participants to improve self-awareness and emotional intelligence. This awareness helps them find the space between stimulus and response and choose how they want to respond in varying situations. After creating the foundation with the Energy Leadership model, monthly sessions include team building, communication, work-life integration, goal setting, empathy, strategic diet and exercise, posture for the surgeon/ergonomics, stress reduction techniques, and mindfulness/meditation. As part of the program, the residents take an assessment called the Energy Leadership Index, which measures self-awareness and emotional intelligence. It measures a value called the *average resonating level (ARL).* Higher ARLs are associated with greater self-awareness and emotional intelligence. As the ARL increased, exhaustion and cynicism decreased and professional efficacy increased. Likewise, perceived stress and depression decreased.[15] In the program's first year, the mean ARL increased. At the same time, perceived stress, depression, and emotional exhaustion decreased; professional efficacy increased; and residents' evaluation of the program on the annual Accreditation Council for Graduate Medical Education (ACGME) survey as positive or very positive increased from 80% to 96% after implementation of the program. Resident satisfaction with personal freedom, work-life balance, communication skills, leadership ability, productivity, time management, and work relationships all increased.[15]

Executive Coaching

Executive coaching is a potential developmental tool for surgeons. Coaching can help surgeons achieve their full potential by (1) increasing self-awareness and emotional intelligence; (2) helping individuals clarify their goals and priorities, breaking down goals into manageable steps, and providing accountability; (3) helping individuals identify potential blind spots; (4) addressing imposter syndrome, improving confidence, and defining self-worth; (5) improving communication; (6) improving ability to function optimally in teams; (7) helping successfully integrate their work and personal lives; and (8) helping people transition throughout their career as they take new responsibilities or their priorities shift.

Historically, coaching in surgery has often been remedial, focused on the struggling or disruptive surgeon, resulting in a negative stigma associated with coaching. Coaches are often brought in to salvage a situation that is already far gone instead of in a preventive setting as a strategy to set people up for success. However, surgeons at all levels can benefit from coaching as a developmental tool. As surgeons embark on their careers, change jobs, or step into new leadership roles, interactions in the first few months of the new positions can determine their success. When initial impressions are good, it can be easier for the surgeon to recover from missteps and vice versa. More jobs are lost because of failures in these nontechnical skills than because of technical incompetence. Early coaching can address these issues before they damage a surgeon's career.

SHIFTING OF PRIORITIES AND MAJOR LIFE STRESSORS

Because of the duration of surgical training and the amount of time a surgeon spends in their commitment to the care of patients, the work and profession are often a considerable part of the surgeon's identity. However, there are many other aspects of a surgeon's life. If a surgeon struggles in any aspect of their life, it affects their performance in other areas and keeps them from reaching their full potential. Therefore, nurturing these multifaceted parts of their lives is critical. This includes hobbies, family, athletics, and the many other aspects of their lives that make them well rounded. Coaches may help surgeons integrate and manage stress in all aspects of their lives and develop an identity outside medicine.

As surgeons progress through their lives and careers, their priorities constantly shift. Sometimes, these shifts are acute. The surgeon gets ill, has a child, gets married, loses a loved one, or faces a global pandemic. Other times, those shifts are more subtle and insidious. The latter is often harder to recognize and address because there is significant inertia to continue to move on the path the surgeon is already on and changing directions can be challenging. Coaches can help surgeons recognize the subtle and acute shifts in priorities and guide them in working to realign the time and energy spent with their priorities as they shift. This is especially important during critical life and career transitions.

Furthermore, in a surgeon's lifetime, they will undoubtedly encounter "pivot points" or events, often out of their control, that challenge them and shape who they are—illness, divorce, loss, family challenges, devastating events in their surgical career, and so on. Kintsugi is a Japanese art form and process in which pottery is wrapped in a cloth, broken with a hammer, and put back together with beautiful gold filler in the cracks. The process is introspective and deliberate. The hammer symbolizes these challenges or pivot points in our lives that change us and define who we are; the cloth represents the things or people that hold us together during those difficult times. During the process, the artist sits with pieces and decides which pieces fit and which no longer fit. The final product represents the strength and beauty we gain from going through those experiences, emotions, and challenges and emerging on the other side. The cracks are highlighted, and the final product is beautiful and strong in its own right. The hardest part for surgeons is to sit with the pieces. They want to rush in and fix it, to clean up the mess quickly and hope nobody sees it. But rather than rush, a critical part of the process is sitting with the pieces and deciding how you want to put them back together, deciding which pieces fit, which no longer fit, and what you want your life to look like moving forward. Our ability to navigate these pivot points is critical, and support during these times is essential.

Frustration with the system we work in and the ever-increasing personal and organizational pressure is common and expected, but not burnout. However, repeated and prolonged exposure to these stressors can contribute to burnout. Moreover, our ability to respond to frustration and our resilience may protect against burnout.

Burnout and Consequences

Burnout among surgeons is a significant concern, with studies indicating high prevalence rates. Research by West, Shanafelt, and others highlights that burnout is more common among physicians than among other US workers.[16,17] A national study of 7905 surgeons reported a burnout rate of approximately 40% among US surgeons.[18] Furthermore, Golisch et al. emphasize the unique aspects of surgery, including longer hours, life-and-death situations, and moral injury associated with surgical complications that dictate rates of burnout among general surgeons and surgical trainees, indicating the need for a multilevel approach to address this issue.[19] The impact of burnout on surgeons' well-being is also evident in studies that discuss the high prevalence of burnout, depression, and suicide among orthopedic and vascular surgeons.[20,21] Beyond the personal consequences, burnout also affects patient care. Burnout has been linked to medical errors, decreased patient satisfaction, and decreased productivity.[22] Coleman et al. report that age, work-related physical pain, and work-home conflicts are independent factors associated with burnout in surgeons.[20] Burnout prevalence was significantly increased during the COVID-19 pandemic. Although some factors that contribute to burnout may be weighted differently between academic (i.e., teaching and academic pursuits) and community surgeons (i.e., business, payer environment), the overall individual and external factors contribute in all surgeons. The literature also emphasizes the need for proactive measures to prevent burnout and maintain well-being among surgeons. These findings underscore the urgency of addressing burnout in general surgeons to ensure the sustainability of the surgical workforce and the quality of patient care.

Mental Health Support

Although burnout and mental health disorders are correlated, you can, and often do, have one without the other. Burnout is a risk factor for depression, but an important distinction must be made. Strategies for improved job satisfaction, wellness, and well-being should not replace the diagnosis and treatment of mental health disorders. Mental illness among all physicians is escalating worldwide and worsened after the COVID-19 pandemic because of global staffing shortages, high patient acuity, and rampant and sustained moral injury.[23] Repetitive workplace traumatic exposures and increasing workload, coupled with a culture that stigmatizes mental health issues and seeking help, have contributed to high rates of diagnosable mental health disorders (depression, anxiety, posttraumatic stress disorder, substance abuse) and suicidal ideation among medical professionals.[24,25]

Suicide is the only cause of mortality that is higher in physicians than in nonphysicians. Increasing rates of untreated mental illness and substance use disorders, both risk factors for suicidal ideation, likely contribute to 300 to 400 physician deaths by suicide each year in the United States.[26] In a systematic review of worldwide physician deaths by suicide, physicians in the United States had a higher rate of suicide, and, unlike the general population, female physicians died more often than male physicians; surgeons had the highest suicide rates among physicians.[27]

In 2008, the American College of Surgeons (ACS) led the first large-scale assessment of suicide and suicidal ideation among surgeons in the United States. At that time, 1 in 16 surgeons reported thoughts of suicide in the previous 12 months.[26] A recent survey of physicians, of which 3% were surgeons, suggests that rates of suicidal ideation and suicide have been increasing in recent years.[28,29] In a survey of surgeons and surgical trainees in 2023, 1 in 7 respondents had thoughts of suicide in the prior year, and 1 in 10 had thought of suicide at least once in the last 2 weeks.[30] Hughes et al. reported that 32% of surgical interns with no prior history of depression met the criteria for moderate to severe depression at least once during their first year of training, and 64% had persistent depression at multiple time points throughout that first year of training. In this same study, only 27% of those meeting the criteria for depression sought formal mental health treatment.[31]

Stigma and fear of job security create tremendous barriers to reporting and seeking help for mental illness among physicians.[32] Department and institutional leadership should engage state mental health resources and physician health programs to understand the resources available specific to their state and work to strengthen the resources if and where they are lacking. The Federation of State Physician Health Programs (https://www.fsphp.org) intends to support physicians and provide anonymous evaluations, not to punish physicians. Most participants in monitoring programs have a successful return to work and are not known to the licensing board while under evaluation and monitoring. Understanding institutional and state resources before a crisis is critical and should be considered an essential knowledge set for surgical leaders to avoid further stigmatizing necessary and potentially lifesaving treatment for surgeons in crisis.

Policies such as the Dr. Lorna Breen Health Care Provider Protection Act represent positive steps toward dismantling barriers to accessing care and destigmatizing mental health disorders.[33,34] Signed into law in March 2022 in response to a physician suicide during the COVID-19 pandemic, the law requires the secretary of Health and Human Services (HHS) to establish and disseminate evidence-based strategies to improve mental health, prevent suicides among healthcare professionals, and reduce the stigma of getting help as well as systematically review the effectiveness of these funded programs. To date, the Dr. Lorna Breen Heroes' Foundation (https://drlornabreen.org) has audited medical boards, resulting in many states in the United States removing the intrusive language from their licensure applications (Fig. 18.4).[35] This includes changes to licensure applications to address mental and physical conditions as one (or not at all) and

having safe-haven, no-reporting options to physicians receiving care through state physician health service or private treatment programs. The Joint Commission recently released a statement to remove barriers to mental healthcare for all healthcare professionals by strongly encouraging institutions not to ask about a clinician's mental health history or treatment as part of hiring or credentialing processes.

Discussions of mental health remain taboo in surgery. We must intentionally work to destigmatize mental health disorders. In addition, surgeons must train for and learn from tragic events, including the deaths of our colleagues. Surgeons must shift to equating mental health as part of overall health, acknowledge substance use disorders as mental health, and understand that mental health struggles do not equate to weakness or lack of competence. Although it is a commonly held belief that asking about self-harm increases the risk, the opposite is actually true. Recognition and questioning about the potential for self-harm lead to reductions in ideation/self-harm behavior.[36] Establishing a plan and resources before a crisis is critical.

Surgical trainees represent a particularly at-risk population at increased risk of mental health disorders and have limited time and money to support treatment. Institutional- and individual-level support for trainees is critical to mitigating harmful health effects, breaking a cycle of perpetuating stigma around mental health and ensuring quality patient care continues to be delivered by these vital members of the healthcare workforce.[16] Resources need to be provided not only to trainees who find themselves in crisis and require acute intervention but also in a preventive model to encourage the development of healthy coping mechanisms, peer support networks, and care-seeking behaviors. Actionable efforts may include widespread completion of psychological first aid training to improve the understanding of the causes and treatments for mental health disorders and increase comfort in recognizing and supporting those who are struggling, educating and reinforcing person-first language (e.g., a person with substance use disorder), prioritizing wellness of surgeons as much as the health of our patients, and openly communicating anonymous resources for crisis intervention.

Some interventions at the individual level, including peer support groups and psychological first-aid training, have shown benefits.[37–39] Several residency programs are implementing and studying the impact of opt-out process groups for trainees in individual and group formats. Although individuals may opt out of the sessions, the protection of time and the facilitation of scheduling during that protected time convey that care for one's mental health is as important as studying and preparing for a future surgical career. Additionally, the use of mentorship teams at key transition points to discuss critical elements of professional development (i.e., clinical efficiency, academic promotion) and the addition of wellness representatives to ask questions about how a person is adjusting, feeling, or managing life outside of the hospital are being adopted at select institutions nationwide.

Culture of Wellness

Although surgeons can develop personal resilience, organizations must create an intentional culture that promotes well-being and supports behaviors that improve surgeon health. As stated previously, fastidious self-care and the development of personal resilience are insufficient to overcome toxic environments. The importance of culture cannot be overstated. Culture sets the tone for what is acceptable, and culture drives resident, faculty, student, and staff behavior. A culture supporting surgeon well-being leads to an engaged surgical workforce, ultimately creating a workplace that benefits all surgical team members. We can all appreciate that in a toxic environment, whether personal or professional, a disproportionate amount of mental energy is consumed thinking about that environment.

In a positive culture, members of that culture have incremental energy to do other meaningful and valuable work. These critical contributions to hospital systems include generating work relative value units (wRVUs), regulatory compliance, high-quality care, and patient satisfaction. Perhaps more importantly, when a culture intentionally improves the environment for all, benefactors of that environment have more energy and motivation to make meaningful contributions to sustain that culture. Perhaps the best news for surgeons is that culture is local, and surgeons tend to lead locally. Although system-level issues may be out of our control, surgeons in departmental, hospital, or residency leadership positions can develop an intentional culture that supports the well-being of students, residents, faculty, and staff.

What follows are several potential opportunities for improving culture within surgery, including inclusive medical leave policies, maternity and paternity leave, and pauses in the tenure clock to allow surgeons the time and space to develop and maintain all aspects of their personal and professional well-being.

Leave Policies (Maternity, Paternity, Health)

Medical leave, whether for changes in maternity or paternity status or personal healthcare, should not only be available but required. Rather than perpetuating the old maxim that "being on call every other night means you miss half the good cases," we should acknowledge that surgical careers are long, ideally lasting 30 to 40 years, and sustaining one's health during this time is necessary to ensure a surgeon is healthy enough to do the job they love for the duration of their career. Although most institutions have legally required leave policies that human resource professionals primarily manage, surgeons must model self-care and healthy behaviors to each other and create environments of compassion and support in which surgeons are encouraged to seek help when needed. In the case of maternity and paternity leave, if we are going to be a profession that welcomes and seeks to equalize males and females in our field, we must create leave policies and local culture that do not punish birthing parents financially or psychologically for taking leave that is, frankly, standard in every profession and every economically developed nation throughout the world.

Pregnancy-Related Challenges in Surgery

Rangel et al. reported significantly worse fertility, more preterm labor, more significant delay in pregnancy because of training, increased use of assisted reproductive technology, and higher pregnancy-related complications in female surgeons than the female partners of their male colleagues.[40] A concomitant increase in postpartum depression was also noted. Given the length of surgical training, many female surgeons delay pregnancy, making fertility even more challenging. Medical insurance or institutions rarely cover egg retrieval/storage, in vitro fertilization (IVF), and childcare. There are many things that programs can do to support females through pregnancy, including "opt-out" maternity leave, faculty education on egg retrieval/storage/IVF, sufficient facilities for lactation, a culture that is comfortable with residents/faculty taking lactation breaks from the operating room or clinics, and adaptation of schedules during pregnancy (similar to any physical or mental health diagnosis).

Leave Policies

There are many situations in which surgeons need leave, and institutional leave policies should include maternity leave, paternity leave, physical- and mental health–related leave, and sabbaticals. We would also recommend that leave policies be "opt-out" versus "opt-in." Many surgeons may need or want time off but worry about taking it because of its impact on others who need to absorb the extra work, fear of appearing weak, or fear of creating inequity or resentment among their colleagues. Opt-out policies would automatically provide leave in given situations, setting the culture and tone for what is expected. At the same time, leaders must set both examples and expectations and, to the extent they can, ensure that faculty, residents, and staff have appropriate time off and accommodations to recover from stressors, including mental health, physical health, and bereavement. Both setting examples and expectations contribute to a culture that encourages self-care.

Second Victim Programs

Surgeons often experience major intraoperative or postoperative adverse events that not only affect our patients but also cause acute mental, emotional, or spiritual distress. When this occurs, there are seldom support systems in place, and surgeons are rarely granted the mental and emotional space to heal. Surgeons have unique relationships with patients because we are trusted to make decisions for them when they are most vulnerable—under anesthesia and unable to make decisions themselves. As such, surgeons are prone to feelings of sadness, guilt, and anxiety when involved in major adverse events.[41]

The term *second victim* refers to a healthcare provider who suffers emotional distress after an adverse event or medical error. Although we have conferences like morbidity and mortality conferences and understand the impact of medical errors on our patients, we often underestimate these events' effects on healthcare professionals. The use of the term *second victim* is controversial because some believe it suggests passivity or stigma for the involved surgeon and deemphasizes the experience of patients and families; however, the importance of emotional support for clinicians continues to gain visibility.[42]

Creating programs that support healthcare professionals experiencing adverse events may be considered a component of a wellness culture. The Massachusetts General Hospital developed such a program to support physicians. It included systems for identifying major adverse events, training peer supporters, and designing a systematic intervention plan.[43] In its initial year, 47 opportunities for intervention were identified for either faculty or training physicians. Of those opportunities identified, 19% of involved providers opted out of receiving support. Among those who did participate, most expressed satisfaction with the program's confidentiality, the safe/trusting environment it provided, and the timeliness of the intervention (89%, 73%, and 83%, respectively). More than 80% suggested that the program positively affected them personally and reflected the department's cultural values of safety and support. Most participants said they would recommend the program to a colleague. Additionally, participants identified an ongoing need to improve the identification of events requiring outreach and the desire for increased awareness of the program throughout the department.[43]

Efficiency of Practice

To this point, we have focused on aspects of individual health and well-being and on the role of culture in improving surgeon health. However, it is essential to think about the increasingly complex healthcare delivery system in which surgeons practice. Whether practicing as part of a small surgical practice, a large academic medical center, or any of the myriad practice settings in between, there are aspects of how healthcare is delivered that threaten the sustainability of the physician workforce. Although we cannot solve all of the following problems, surgical and hospital leaders can ease the pain points and improve practice efficiency. Some practice solutions have been implemented or proposed that serve to improve the health and well-being of surgeons and safeguard the future health of the surgical workforce.

Addressing Challenges in Modern Healthcare Delivery to Promote Physician Health and Well-Being

Organizations must recognize that surgeon well-being is essential to high-quality patient care. Burnout and poor health and well-being of surgeons affect the personal lives of individual healthcare professionals. Burnout is associated with compassion fatigue, career dissatisfaction, job turnover, divorce, disruptive behavior, home or workplace violence, depression, and suicide. It also negatively affects quality of care, patient safety, patient satisfaction, and productivity. Although the frequency of overnight calls, practice setting, method of compensation, and number of hours worked were not associated with errors, each 1-point increase in depersonalization on the Maslach Burnout Inventory was associated with an 11% increase in the likelihood of reporting an error, and each 1-point increase in emotional exhaustion was associated with a 5% increase in the probability of reporting a medical error. Depression was also an independent predictor of reporting a recent major medical error on multivariate analysis that controlled for other personal and professional factors.

Additionally, physician turnover due to burnout is expensive. One analysis of the cost attributable to physician burnout is approximately $4.6 billion annually in the United States.[44] Consider an organization with 450 physicians with an annual turnover rate of 7.5% and an average replacement cost of $500,000 per physician. This organization would incur over $5 million annually related to burnout-associated physician turnover.

Functional Teams and Team Models of Care

Various team models of care in surgery have been proposed, particularly as we emerge from the COVID-19 pandemic. During the pandemic, surgeons were forced to adopt call and care models that supported the surging number of critically ill patients and the clustering of healthcare professionals to limit exposure and transmission of the coronavirus between healthcare workers.

Outside of the circumstances of the COVID-19 pandemic, the term *team models of care* may mean different things to different healthcare delivery systems and different surgical subspecialties. In the following sections, we discuss several proposed alternatives or modifications to traditional models of surgical care delivery that emphasize single surgeons as the sole individuals who can provide care to their patients.

Intradisciplinary Collaborative Team-Based Models

Although there is a significant commitment to interdisciplinary care, such as that which exists between medical oncology and surgical oncology or between gastroenterology and colorectal surgery, more attention needs to be paid to intradisciplinary collaboration. Essentially, intradisciplinary partnership leverages the familiar concepts of group practice and call coverage in a more streamlined way. This concept builds on the recognition that team-based care models can improve access and patient care while also harnessing the collective power of a team to allow team members (including physicians) to have time away with the confidence that their clinical practices will be appropriately managed in their absence. One proposal for creating a truly intradisciplinary team-based approach to surgical care involves grouping same-specialty surgeons into teams and then consolidating administrative resources (i.e., clinic, hospital, and operating room space), nursing support, and educational responsibilities within these subspecialty units.[45]

The most extreme version of such a team-based model is the single-entry model. It takes the previous model and employs the queue framework, requiring patients to be scheduled with the first available surgeon with a practice profile that matches their diagnosis. This model has some advantages of improving access for surgical patients. However, it may strike a negative chord with many because it does not allow for the amount of choice for patients or providers we are accustomed to in many current healthcare delivery systems.

Large Group Practices

An increasing number of surgeons are practicing within group practices. Group practices have improved patient, physician, and health system outcomes. The benefits to physicians include enhanced quality of life and income, though they may also introduce challenges when interpersonal conflict develops between group members.[46] In recent years, a trend toward increasing practice size has been noted, which may positively influence surgeon health and well-being. This relative growth in practice size is noted even among specialists, like orthopedics and neurosurgery, who traditionally have smaller practice sizes. Although the drivers of these trends are likely based on changes in hospital networking and consolidation of health systems and may have varied impacts on the quality of care and access to care, there are potential benefits to surgeons and the surgical profession that should continue to be investigated.

In very practicable terms, having group sizes that are large enough to ensure ample cross-coverage and the capacity to entrust the care of patients between team members is imperative to allow for necessary time away from work to rest and recharge for all team members. Practice redundancy combined with standardization or an algorithmic approach to common surgical scenarios agreed on by all team members while remaining affordable for healthcare systems should be a goal for surgical and health system leaders. Although increasing practice size is only feasible in some settings, organizations would benefit from creating similar cooperation and cross-coverage to improve well-being, even for independent or small group practices.

In the academic setting, in which the mission or job function of the surgeon includes scholarly or educational activities, leveraging the group size to manage wRVU expectations in light of these other responsibilities should be strategic and intentional. In larger groups, members with time and salary supported by other roles or funding should be supported, with time truly protected, to prevent the collapse of these missions, which are critical to the perpetuation of academic surgery. Supporting surgeons in their pursuit of nonclinical work requires teams large enough to support collective wRVU goals rather than individual wRVU goals. This also requires a culture committed to growing an entire department or division across multiple missions and supporting each team member in their unique contribution to these missions.

Interdisciplinary Teamwork

Teamwork between surgeons and nonsurgeon colleagues has been shown to improve patient outcomes and also stands to improve surgeon health and well-being. Research evaluating complex surgical patients has consistently demonstrated that those treated in hospitals with high physician teamwork between surgeons and nonsurgeons were found to have better outcomes, even when controlling for hospital and patient factors. Similar to high-functioning, *intradisciplinary* teams, the presence of high-functioning *interdisciplinary* teams allows the often all-consuming care of complex patients to be distributed among multiple competent physicians and allows specialists to focus on their expertise rather than trying to manage all aspects of patient care. This model can be best appreciated in transplant surgery, where medical and surgical experts in the complex trajectory of transplant patients before and after transplant are integrally involved in care teams. Hospital systems increasingly incorporate service lines (e.g., oncology, transplant, digestive diseases) to leverage interdisciplinary care.

Advanced Practice Professionals

Additional research demonstrates that integrating advanced practice professionals (including nurse practitioners and physician assistants) improves patient care and can relieve a significant burden on surgeons. Integration of these professionals not only improves healthcare quality in the form of reduced rates of complications and readmission and reduced episode spending in single-specialty surgical practices but may also have positive implications for staffing models in inpatient and outpatient practice environments.[47,48] The addition of these professionals to surgical practices allows surgeons to optimize their time doing the aspects of their profession that are truly unique to their highly trained skill set while having highly trained and highly valuable team members to oversee the breadth of care required to take care of surgical patients.

Optimizing Use of the Electronic Medical Record

The EMR, including ambulatory, inpatient, and operative care documentation, is frequently cited as a source of burnout and low sense of well-being. Many strategies may help mitigate the vast demands on time created by the EMR. One-on-one, real-time physician instruction to create functional templates and shortcuts tailored to their practice can save significant time and improve documentation quality.

Scribes and Medical Assistants/Support Staff

Using scribes in surgical practices has decreased time spent in the EMR per patient visit and improved physician well-being. The presence of a scribe in a surgical clinic allows more patients to be seen and improves surgeon well-being across many scales of emotional, spiritual, physical, and intellectual well-being. Surgeons working with scribes report increased time and capacity to educate learners and provide patient education during the clinic visit.[49] Additionally, using scribes in surgical clinics may improve work satisfaction, which has a presumed positive impact on overall well-being. Also, scribes increase the timeliness of note completion, decreasing delinquent notes and delayed billing, thereby improving the revenue cycle. In addition to scribes, which may offload much of the documentation burdens physicians face, there is growing support that effective teams of medical assistants and clinic nurses to support additional EMR-related tasks stand to reduce burnout related to the EMR.[50] Many creative models can be used to employ scribes. Scribe costs can be offset with productivity dollars in systems where productivity drives incentives.

CONCLUSIONS

To improve the experience for the next generation of surgeons and sustain the future of the surgical workforce, there needs to be a focus on the prevention of burnout and support for accumulated moral injuries; this is the responsibility of both health systems and individuals. Although surgical training must remain rigorous to continue training surgeons to provide essential care, we must think creatively to improve surgical training and surgical care delivery in a way that prioritizes the health of members of the surgical workforce.

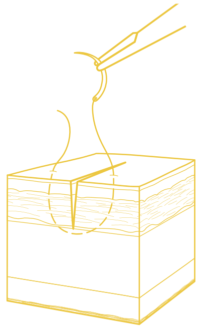
19 CHAPTER

Principles of Preoperative and Operative Surgery

Chioma Moneme, Allan Tsung, Reid B. Adams, and Victor M. Zaydfudim



OUTLINE

Principles of Surgical Evaluation
- Patient-Surgeon Relationship
- Surgical Objectives
- Elective, Urgent, and Emergent Indications
- Risk Assessment
- Informed Consent

Assessment of Geriatric Surgical Patients
- Comprehensive Geriatric Assessment
- Cognitive Impairment and Delirium
- Depression
- Medication Management
- Functional Status and Frailty
- Patient Counseling

Systems Approach to Preoperative Evaluation
- Cardiovascular System
- Pulmonary System
- Renal System
- Hepatobiliary System
- Hematologic System
- Endocrine System
- Nutrition and Obesity

Preoperative Considerations and Care Protocols
- Patient Recovery Pathways
- Antibiotic Prophylaxis
- Review of Medications
- Preoperative Fasting

Operating Room
- Maintenance of Normothermia
- Preoperative Skin Preparation
- Hemostasis
- Wound Closure
- Surgical Adhesives

Surgical Devices, Energy Sources, and Staplers
- Electrosurgery and Electrocautery
- Ultrasonic Dissectors
- Ablation Technology
- Other Energy Devices
- Surgical Staplers

Potential Causes of Intraoperative Instability
- Malignant Hyperthermia
- Gas Embolus: Air and Carbon Dioxide
- Myocardial Infarction, Pulmonary Embolus, and Pneumothorax
- Hemorrhage

Outpatient Surgery

PRINCIPLES OF SURGICAL EVALUATION

Patient-Surgeon Relationship

Clear, precise, and unambiguous communication to establish an understanding of mutual expectations and trust is at the pinnacle of the patient-surgeon relationship. A surgeon's initial encounter with a patient most commonly is in the context of a new diagnosis and is initiated by either a professional referral or self-referral. A history and physical examination, whether in an urgent/emergent or elective setting, should initially focus on confirmation or rebuttal of the suspected diagnosis. Inquiries regarding patients' personal interests and relationships with their community and society help create a common bond between the patient and surgeon. In addition to direct communication with the patient, knowledge of their situation is augmented by a thorough review of relevant diagnostic laboratory and imaging results. Through this process, an experienced surgeon effectively re-creates the clinical context of a patient's situation during the period preceding evaluation for the illness in question.

Further patient management is directed by the differential diagnosis generated during the initial evaluation. If the differential diagnosis contains items of equipoise that require distinct treatments, further investigations may be necessary to distinguish between these options. In general, the principle of Occam's razor or parsimony applies to surgical diagnosis and management; it is important to pursue only those diagnostic studies that have a high likelihood of producing actionable results. Tests with a near-perfect pretest probability and those unlikely to alter treatment should be avoided. Once a diagnosis is secured, the objective and urgency of potential surgical therapy are considered.

Surgical Objectives

Achieving a joint understanding of surgical objectives and expectations between patient and surgeon is paramount to improve patient satisfaction and outcomes. There are three broad potential objectives of surgical intervention: disease prevention, disease control, and symptom palliation. Examples of operations aimed at disease prevention include prophylactic mastectomy, colectomy, pancreatectomy or thyroidectomy for heritable cancer syndromes, endarterectomy for asymptomatic carotid stenosis, or appendectomy in the setting of Ladd's procedure for intestinal malrotation. These operations are aimed at preempting a disease process. Operations for disease control address a process that is ongoing. Examples include resections for malignancy, cholecystectomy for acute cholecystitis, enterolysis for bowel obstruction, bypass for vascular occlusive disease, or knee replacement for arthritis. With these operations, patients may expect partial or complete resolution of the targeted disease process. Finally, palliative operations are aimed at improving quality of life rather than curing a disease. Examples include proximal decompression for malignant bowel obstruction or gastrojejunostomy for unresectable pancreatic cancer with gastric outlet obstruction. Inadequate communication of an operation's objectives precludes informed consent and can have dramatic, negative implications for a patient's perioperative decision-making.

Elective, Urgent, and Emergent Indications

Appropriate triage of surgical therapy is important for patient outcomes and resource distribution. Accurate categorization of surgical urgency also has implications for quality reporting. The American College of Surgeons (ACS) National Surgical Quality Improvement Program (NSQIP) differentiates between emergency and elective operations and reports different levels of accuracy for patient risk estimates, with emergency cases having both superior predictive accuracy for mortality and significantly higher observed-to-expected ratios. Within ACS NSQIP, emergency surgery is characterized by an ongoing acute process that can result in rapid deterioration in a patient's condition, for which unnecessary delay can potentially threaten the clinical outcome. On the other hand, elective operations generally involve a patient who has completed preoperative surgical evaluation during a separate patient-surgeon encounter and is subsequently scheduled for an operation. Inpatients, referrals from the emergency department, and direct transfers from the clinic are excluded from elective patient categorization. Urgent operations are a relatively ill-defined category and have an acuity level in between those of elective and emergent cases. The World Society of Emergency Surgery created the Timing of Acute Care Surgery (TACS) classification in 2013, which subdivides urgent cases into those with an ideal time to surgery falling between immediate and within 48 hours from diagnosis. In 2023, this same group sought to improve the TACS classification and validate the new classification using the Delphi method. The new TACS provides more clarity in the process of classifying patient disease severity and classifies urgent cases into an ideal time to surgery between immediate and within 4 days after diagnosis. Recognition of urgency should be one of the first steps of the preoperative surgical evaluation because it affects subsequent patient decision-making, counseling, investigatory testing, and perioperative management.

Risk Assessment

Perioperative risk assessment has an impact on all aspects of surgical planning, including the decision to operate, choice of operation, perioperative management, and goals-of-care discussions. Communication with patients regarding the risks of a proposed operation must be coupled with a thorough review of patient comorbidities and functional status. Hence, patients with prohibitively high operative risk can be protected from inappropriate operations, whereas those with borderline risk can be medically optimized preoperatively. From the viewpoint of perioperative management, appropriate risk stratification facilitates resource allocation, including intraoperative monitoring, use of intensive care unit services after the operation, and potential use of medical consultation. Finally, transparent categorization of patient risk factors improves institutional reporting and allows for multi-institutional comparisons of risk-adjusted patient outcomes.

Risk assessment begins by considering the nature of the disease and patient comorbidities while weighing the risks of possible surgical interventions. For a number of diagnoses, multiple surgical approaches may be available, each with advantages and disadvantages in terms of the morbidity profile, quality outcomes, and durability of the therapy. These must be weighed carefully in the context of each patient's presenting condition and baseline level of health. The American Society of Anesthesiologists (ASA) physical status (PS) categorization has frequently served as a simple, initial rubric to summarize baseline patient comorbidity. Patient categorization into ASA I–VI (Table 19.1) helps stratify patients as low

TABLE 19.1 American Society of Anesthesiologists Classification of Physical Status (ASA PS)

ASA PS CLASSIFICATION	DEFINITION	ADULT EXAMPLES, INCLUDING BUT NOT LIMITED TO
ASA I	A normal healthy patient	Healthy, nonsmoking, no or minimal alcohol use.
ASA II	A patient with mild systemic disease	Mild diseases only without substantive functional limitations. Current smoker, social alcohol drinker, pregnancy, obesity (BMI between 30 and 40), well-controlled DM/HTN, mild lung disease.
ASA III	A patient with severe systemic disease	Substantive functional limitations; one or more moderate to. severe diseases. Poorly controlled DM or HTN, COPD, morbid obesity (BMI >40), active hepatitis, alcohol dependence or abuse, implanted pacemaker, moderate reduction of ejection fraction, ESRD undergoing regularly scheduled dialysis, history (>3 months) of MI, CVA, TIA, or CAD/stents.
ASA IV	A patient with severe systemic disease that is a constant threat to life	Recent (<3 months) MI, CVA, TIA, or CAD/stents; ongoing cardiac ischemia or severe valve dysfunction; severe reduction of ejection fraction; shock; sepsis; DIC; ESRD not undergoing regularly scheduled dialysis.
ASA V	A moribund patient who is not expected to survive without the operation	Ruptured abdominal/thoracic aneurysm, massive trauma, intracranial bleed with mass effect, ischemic bowel in the face of significant cardiac pathology or multiple organ/system dysfunction.
ASA VI	A declared brain-dead patient whose organs are being removed for donor purposes	

The addition of "E" denotes emergency surgery. An emergency is defined as existing when delay in treatment of the patient would lead to a significant increase in the threat to life or body part.

BMI, Body mass index; *CAD,* coronary artery disease; *COPD,* chronic obstructive pulmonary disease; *CVA,* cerebrovascular accident; *DIC,* disseminated intravascular coagulation; *DM,* diabetes mellitus; *ESRD,* end-stage renal disease; *HTN,* hypertension; *MI,* myocardial infarction; *TIA,* transient ischemic attack.

TABLE 19.2 Risks of Cardiac Events Depending on the Type of Operation

LOW RISK: <1%	INTERMEDIATE RISK: 1%–5%	HIGH RISK: >5%
Superficial surgery	Intraperitoneal: splenectomy, hiatal hernia repair, cholecystectomy	Aortic and major vascular surgery
Breast	Carotid symptomatic (CEA or CAS)	Open lower limb revascularization or amputation or thromboembolectomy
Dental	Peripheral arterial angioplasty	Duodenopancreatic surgery
Endocrine: thyroid	Endovascular aneurysm repair	Liver resection, bile duct surgery
Eye	Head and neck surgery	Esophagectomy
Reconstructive	Neurologic or orthopedic: major (hip and spine surgery)	Repair of perforated bowel
Carotid asymptomatic (CEA or CAS)	Urologic or gynecologic: major	Adrenal resection
Gynecology: minor	Renal transplant	Total cystectomy
Orthopedic: minor (meniscectomy)	Intrathoracic: nonmajor	Pneumonectomy
Urologic: minor (transurethral resection of the prostate)		Pulmonary or liver transplant

CAS, Carotid artery stenting; *CEA,* carotid endarterectomy.

risk,[1,2] intermediate risk,[3] high risk,[4,5] and brain dead.[6] The addition of "E" designation signifies emergent operation, hence indicating a higher risk. First introduced in 1941, increasing ASA class was shown in a number of landmark studies to be associated with early postoperative mortality. This relationship remains true in the modern era for both emergent and elective operations, with class VE associated with a nearly 20% likelihood of early postoperative mortality.

Next, operations can be categorized into low-, intermediate-, and high-risk groups. This categorization is most commonly approached through expert opinion and consensus guidelines, such as those proposed by the European Society of Cardiology and European Society of Anesthesiology, which stratifies patients based on estimated 30-day risk of cardiac events (Table 19.2). Combination surgical risk models, including patient comorbidity and operative risk, have been developed using logistic regression, with mortality or major complication as the dependent variable.[5] For very low-risk outpatient procedures, the risk of death is less than 1 in 50,000; conversely, high-risk operations performed for life-threatening conditions in critically ill patients can have expected mortality rates routinely exceeding 20% (Fig. 19.1).

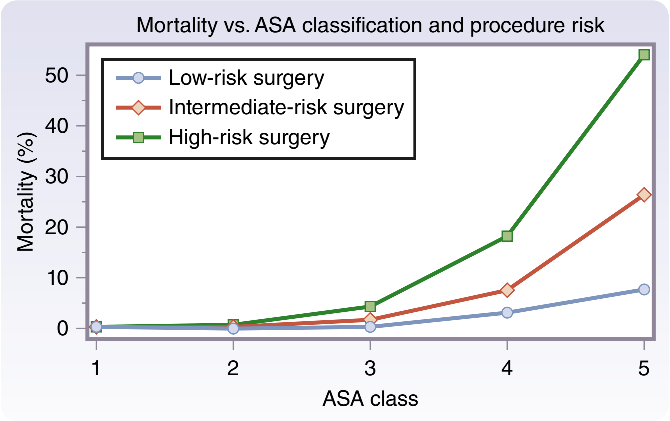

FIGURE 19.1 The observed mortality rate as a function of the American Society of Anesthesiologists *(ASA)* physical status and surgery-specific risk. (Adapted from Glance LG, Lustik SJ, Hannan EL, et al. The surgical mortality probability model: derivation and validation of a simple risk prediction rule for noncardiac surgery. *Ann Surg.* 2012;255:696-702.)

A wide variety of tools can help quantify operative risk in the preoperative setting. These tools can predict risks of broad outcomes, such as death or length of stay, or specific events, such as reoperation, intraoperative blood loss, or specific surgical complications. From a methodology standpoint, these tools can be grouped into categorical scales, risk scores, or prediction models. Categorical scales are easy to calculate and frequently subjective. The most classic example of a categorical scale is the ASA PS classification frequently used in preoperative risk estimation. Surgical risk scores combine several predictors, usually chosen using multivariable predictive modeling, to estimate risk of a specific outcome. An example of a risk score is the Model for End-Stage Liver Disease (MELD) score used to predict short-term prognosis in patients with end-stage liver disease.[6] More recently, the adoption of advanced statistics to analyze large, multi-institutional datasets has created numerous risk prediction models that account for patient-level risk factors to generate estimated likelihoods of multiple surgical outcomes. The most commonly used and cited example of a surgical risk score is the ACS NSQIP Surgical Risk Calculator (SRC).

The ACS NSQIP universal SRC was developed in 2013 using standardized clinical data from more than 500 NSQIP participant hospitals.[7] This online tool predicts adverse postoperative outcomes based on 20 preoperative patient-level characteristics, including demographics and comorbidities (Table 19.3). Risks associated with procedure type are incorporated using Current Procedural Terminology (CPT) codes. Three of the outcomes are associated with specific CPT codes related to vascular procedures, proctectomy, and pancreatectomy. Those outcomes are designated in the calculator with "T." Recalibrated in 2016, the database more accurately predicts outcomes for lowest- to highest-risk patients.[8] It currently contains data from more than 5 million cases across 874 hospitals and is publicly accessible at http://riskcalculator.facs.org. Originally designed to predict 8 postoperative adverse outcomes, the tool has evolved to currently report likelihoods of 18 specific or composite outcomes within 30 days of surgery:

- Serious complication (e.g., cardiac arrest, myocardial infarction [MI], pneumonia)
- Any complication (surgical site infections [SSIs], pulmonary embolus [PE], ventilator >48 hours)
- Pneumonia
- Cardiac complication
- Surgical site infection

TABLE 19.3 ACS NSQIP Variables Used in the Colon-Specific and the Universal Surgical Risk Calculator

VARIABLE	CATEGORIES	COLON SPECIFIC	UNIVERSAL
Age group, years	<65, 65–74, 75–84, ≥85	✓	✓
Sex	Male, female	✓	✓
Functional status	Independent, partially dependent, totally dependent	✓	✓
Emergency case	Yes, no	✓	✓
ASA class	I or II, III, IV, or V	✓	✓
Steroid use for chronic condition	Yes, no	✓	✓
Ascites within 30 days preoperatively	Yes, no	✓	✓
System sepsis within 48 h preoperatively	None, SIRS, sepsis, septic shock	✓	✓
Ventilator dependent	Yes, no	✓	✓
Disseminated cancer	Yes, no	✓	✓
Diabetes	No, oral, insulin	✓	✓
Hypertension requiring medication	Yes, no	✓	✓
Previous cardiac event	Yes, no	✓	✓
Congestive heart failure in 30 days preoperatively	Yes, no	✓	✓
Dyspnea	Yes, no	✓	✓
Current smoker within 1 year	Yes, no	✓	✓
History of COPD	Yes, no	✓	✓
Dialysis	Yes, no	✓	✓
Acute renal failure	Yes, no	✓	✓
BMI class	Underweight, normal, overweight, severity of obesity: class 1, class 2, severe class 3	✓	✓
Colon surgery group (colectomy)	Partial lap with anastomosis, partial lap with ostomy, partial open with anastomosis, partial open with ostomy, total lap with ostomy, total open with ostomy	✓	
Indication for colon surgery	Diverticulitis, enteritis/colitis, hemorrhage, neoplasm, obstruction/perforation, vascular insufficiency, volvulus, other	✓	
CPT-specific linear risk	2805 values		✓

ACS NSQIP, American College of Surgeons National Surgical Quality Improvement Program; *BMI,* body mass index; *COPD,* chronic obstructive pulmonary disease; *CPT,* Current Procedural Terminology; *lap,* laparotomy; *SIRS,* systemic inflammatory response syndrome.

- Urinary tract infection
- Venous thromboembolism (VTE)
- Renal failure
- Colon ileus (conditionally displayed based on the selected procedure)
- Colon anastomotic leak (conditionally displayed based on the selected procedure)
- Readmission
- Return to the operating room
- Death
- Discharge to nursing or rehab facility
- Predicted length of hospital stay
- Vascular lower extremity open wound
- Pancreatectomy delayed gastric
- Proctectomy ileus

Levels of discrimination for these outcomes are generally strong, with c-statistics higher than 0.75 for all predicted outcomes. In particular, discrimination for 30-day postoperative mortality is excellent, with c-statistics exceeding 0.9.[8] Recent investigations have evaluated combining ACS NSQIP SRC models with preoperative biologic markers, such as hypoalbuminemia,[9] or with organ-specific metrics, such as chronic liver disease in patients selected for liver resection.[10] The SRC model has also been adapted for the pediatric population. The Pediatric Surgical Risk Calculator incorporates nearly 200,000 cases across 67 hospitals and accounts for 382 CPT codes; it has demonstrated excellent predictive accuracy for mortality and morbidity after operations in children. The ACS NSQIP SRC is specifically designed to facilitate patient counseling and consent before surgery; as such, it does not take into account intraoperative findings. Despite its excellent calibration within the broad ACS NSQIP dataset, studies have identified lapses in predictive accuracy within smaller homogenous patient populations.[11] Therefore, it cannot replace familiarity with institution- and surgeon-specific performance.

Informed Consent

Surgeons have an ethical obligation to discuss and pursue informed consent with any patient considering an operation. Comprehensive, transparent, and clear communication of perioperative risks and potential benefits is mandatory. A critical component of informed consent is discussing and understanding the patient's goals of care and placing these in context with the benefits and risks of the proposed procedure, thereby ensuring shared decision-making with the patient and their family. To successfully guide the patient through the consent process, a surgeon must possess a thorough technical understanding of the proposed operation, the most probable perioperative course, and potential pitfalls and complications. Clear and precise communication of risks and expectations is paramount; technical jargon should be avoided. The consent process must take into account all of the preceding facets of surgical objectives, urgency, and patient risk assessment. Systematic reviews indicate that common components of a consent discussion should include (1) the disease diagnosis, (2) the proposed procedure, (3) procedure-related risks, (4) likelihood of success of the procedure, (5) mental capacity of the patient, and (6) alternative treatment options.[12] One of the most challenging impediments to informed consent is the knowledge gap between surgeon and patient. To overcome this, consent processes can be augmented for specific diseases and procedures using decision aids, visual materials, specialized written materials, and previously discussed risk calculators. In general, these supplementary instruments have been shown to improve patient knowledge and satisfaction with decision-making.[13]

ASSESSMENT OF GERIATRIC SURGICAL PATIENTS

The population of the United States continues to age. The number of adults over the age of 65 years old is expected to increase from 13% of the total population to a staggering 23% by 2030. Geriatric patients account for more than 40% of hospital days, one-third of all inpatient procedures, and incur nearly half of all inpatient hospital charges. The geriatric population presents unique surgical challenges. Tailoring the preoperative workup to the unique needs of these patients can help surgeons address age-related functional challenges and comorbidities. To ensure that decision-making is appropriately aligned between provider and patient, the patient and their family must clearly understand operative risks, potential effects of surgery-related complications on quality of life, and likely outcomes. Conversely, the surgeon must appreciate, value, and incorporate the patient's personal goals of care in any decision-making process and final assessment.

Comprehensive Geriatric Assessment

Chronologic demarcation of the "geriatric" patient is elusive. A combination of advanced age, comorbidities, and functional and/or cognitive decline contribute to the definition of a geriatric patient. Because of the clinical and social complexities of the geriatric population, an appropriate preoperative evaluation is multifaceted. Collaboration between the ACS NSQIP and the American Geriatrics Society (AGS) produced a set of guidelines for the multidomain assessment of geriatric patients.[14] This approach was not novel; the concept of a comprehensive geriatric assessment (CGA) was first implemented in the 1980s and 1990s in medical inpatient and long-term outpatient settings. Geriatric assessments were shown to improve independent living, physical function, and long-term mortality. Studies reporting the implementation of CGA within surgical populations are rare; a recent systematic review found positive impacts of CGA use on procedural cancellation rate, surgical complications, and length of stay.[15] Importantly, historic data demonstrate that the most effective CGA programs are those that affect direct medical care recommendations. The CGA is composed of medical, mental health, functional capacity, social, and environmental domains. The ACS NSQIP/AGS collaborative framework (Table 19.4) refocuses the CGA toward themes more relevant to operative and perioperative care. Although all aspects of the framework are vital, several are more pertinent within the geriatric population considered for surgery.

TABLE 19.4 ACS NSQIP/AGS Collaborative Checklist for Preoperative Assessment of Geriatric Surgical Patient

In addition to conducting a complete history and physical examination of the patient, the following assessments are strongly recommended:

- Assess the patient's **cognitive ability** and **capacity** to understand the anticipated surgery.
- Screen the patient for **depression.**
- Identify the patient's risk factors for developing postoperative **delirium.**
- Screen for **alcohol** and other **substance abuse/dependence.**
- Perform a preoperative **cardiac** evaluation according to the American College of Cardiology/American Heart Association algorithm for patients undergoing noncardiac surgery.
- Identify the patient's risk factors for postoperative **pulmonary** complications and implement appropriate strategies for prevention.
- Document **functional status** and history of **falls.**
- Determine baseline **frailty** score.
- Assess patient's **nutritional status** and consider preoperative interventions if the patient is at severe nutritional risk.
- Take an accurate and detailed **medication history** and consider appropriate perioperative adjustments. Monitor for **polypharmacy.**
- Determine the patient's **treatment goals** and **expectations** in the context of the possible treatment outcomes.
- Determine patient's **family** and **social support system.**
- Order appropriate preoperative **diagnostic tests** focused on elderly patients.

Optimal preoperative assessment of the geriatric surgical patient: a best practice guideline from the American College of Surgeons National Surgical Quality Improvement Program and the American Geriatrics Society. *J Am Coll Surg.* 2012;215:453-466.

Cognitive Impairment and Delirium

Nearly one in five elderly patients have dementia or cognitive impairment. The ACS NSQIP/AGS framework recommends routine neurocognitive assessment for these patients in the preoperative setting. Specifically, the guidelines recommend cognitive evaluation for any geriatric patient without a preexisting diagnosis of cognitive impairment. Methods include cognitive assessments such as the Mini-Cog (Fig. 19.2) and/or interviews with the patient's support structure (spouse or family) or affiliated healthcare providers.[16] The Mini-Cog's advantages include the large body of evidence supporting its usefulness, ease of implementation (3 minutes to complete), and focus on attention and executive function. Any findings suggestive of cognitive impairment should prompt referral to a primary care, mental health, or geriatric specialist. Establishing cognitive impairment early in the preoperative setting has direct implications for patient-physician communication, decision-making capacity, and informed consent.

In the postoperative setting, cognitive impairment strongly predicts delirium, which has an incidence of nearly 50% among geriatric patients. Documentation of preexisting cognitive impairment improves interpretation of perioperative mental status and encourages avoidance of medications that may precipitate delirium. In the geriatric population, postoperative delirium has a profound impact on hospital length of stay, long-term postoperative cognition, cost of care, and mortality.[17] Because evidence-based treatments for delirium are few, the majority of studies focus on the identification of risk factors and prevention. The AGS best practice guidelines for delirium recommend preoperative risk

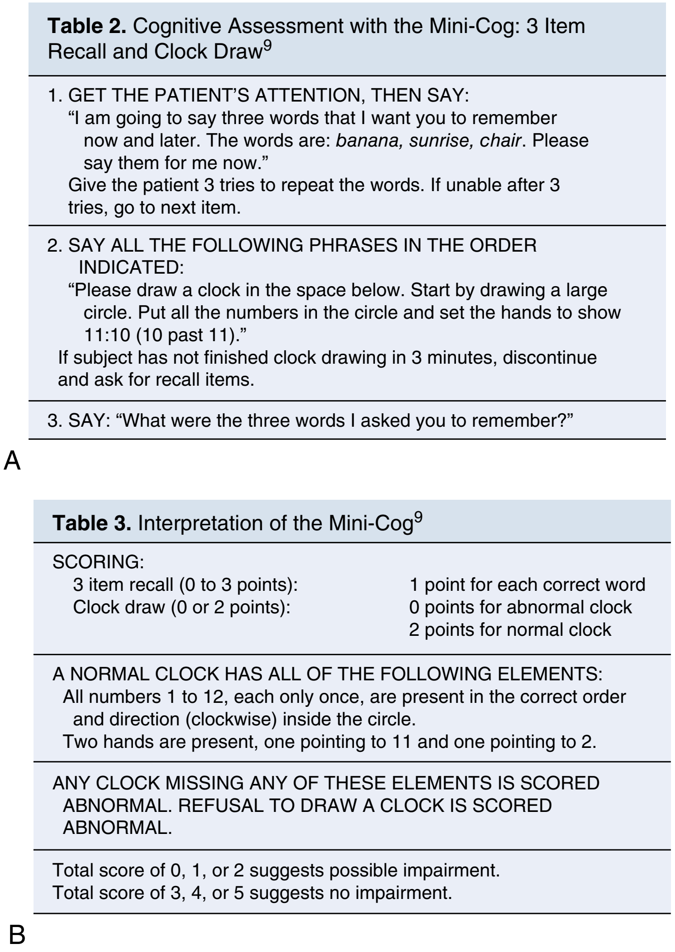

Table 2. Cognitive Assessment with the Mini-Cog: 3 Item Recall and Clock Draw[9]

1. GET THE PATIENT'S ATTENTION, THEN SAY:
"I am going to say three words that I want you to remember now and later. The words are: *banana, sunrise, chair*. Please say them for me now."
Give the patient 3 tries to repeat the words. If unable after 3 tries, go to next item.

2. SAY ALL THE FOLLOWING PHRASES IN THE ORDER INDICATED:
"Please draw a clock in the space below. Start by drawing a large circle. Put all the numbers in the circle and set the hands to show 11:10 (10 past 11)."
If subject has not finished clock drawing in 3 minutes, discontinue and ask for recall items.

3. SAY: "What were the three words I asked you to remember?"

A

Table 3. Interpretation of the Mini-Cog[9]

SCORING:

3 item recall (0 to 3 points):	1 point for each correct word
Clock draw (0 or 2 points):	0 points for abnormal clock 2 points for normal clock

A NORMAL CLOCK HAS ALL OF THE FOLLOWING ELEMENTS:
All numbers 1 to 12, each only once, are present in the correct order and direction (clockwise) inside the circle.
Two hands are present, one pointing to 11 and one pointing to 2.

ANY CLOCK MISSING ANY OF THESE ELEMENTS IS SCORED ABNORMAL. REFUSAL TO DRAW A CLOCK IS SCORED ABNORMAL.

Total score of 0, 1, or 2 suggests possible impairment.
Total score of 3, 4, or 5 suggests no impairment.

B

Optimal preoperative assessment of the geriatric surgical patient: a best practice guideline from the American College of Surgeons National Surgical Quality Improvement Program and the American Geriatrics Society. *J Am Coll Surg*. 2012;215:453-466. *Copyright from S Borson included in JACS publication.*)

factor screening for all geriatric surgical patients[18] (Table 19.5). Identification of these risk factors should raise awareness to avoid second-hit insults (such as high-risk medication administration and sleep cycle disturbance) and to implement simple measures that improve the patient's orientation. Such measures include holding high-risk medications preoperatively, providing hearing aids, encouraging sleep hygiene with preservation of day/night cycle, and employing the help of the patient's family for reorientation during postoperative in-hospital recovery.

Depression

Increased comorbidity and medical burden, conditions highly prevalent in the geriatric population, can exacerbate depressive symptoms. Additional risk factors include female sex, prior diagnosis of depression, sleep disturbance, low functional status, disability, and living alone.[19] Elderly patients with preoperative depressive symptoms can experience postoperative delirium at a significantly higher rate and for a longer duration. Depression also may lower the threshold for pain and is a predictor of chronic postoperative pain. In the intensive care setting, depression is associated with increased mortality and reduced quality of life after discharge. After cardiac surgery, depression and anxiety may increase the likelihood of coronary disease recurrence and mortality after coronary artery bypass graft (CABG). The ACS NSQIP/AGS guidelines recommend the Patient Health Questionnaire-2 (PHQ-2) as a pragmatic preoperative screening tool for elderly patients; positive findings should be followed by appropriate referral. Optimal management of depression requires a multidisciplinary approach frequently involving both psychiatric medications and cognitive behavioral therapy.

TABLE 19.5 **Risk Factors for Postoperative Delirium**
Age greater than 65 years
Cognitive impairment
Severe illness or comorbidity burden
Hearing or vision impairment
Current hip fracture
Presence of infection
Inadequately controlled pain
Depression
Alcohol use
Sleep deprivation or disturbance
Renal insufficiency
Anemia
Hypoxia or hypercarbia
Poor nutrition
Dehydration
Electrolyte abnormalities (hypernatremia or hyponatremia)
Poor functional status
Immobilization or limited mobility
Polypharmacy and use of psychotropic medications (benzodiazepines, anticholinergics, antihistamines, antipsychotics)
Risk of urinary retention or constipation
Presence of urinary catheter
Aortic procedures

Adapted from American Geriatrics Society Expert Panel on Postoperative Delirium in Older Adults. Postoperative delirium in older adults: best practice statement from the American Geriatrics Society. *J Am Coll Surg*. 2015;220:136-148.

Medication Management

The ACS NSQIP/AGS framework emphasizes the importance of obtaining a comprehensive medication history for all older patients, including over-the-counter medications, eye drops, vitamins, and herbal products. Adverse drug reactions, inappropriate dosing, and polypharmacy can be avoided by considering potential changes in drug metabolism and clearance in the perioperative setting.

The American College of Cardiology (ACC) and American Heart Association (AHA) guidelines for perioperative β-blockade supports the continued administration of β-blockers for patients already on this medication. Patients undergoing intermediate-risk surgery with known coronary artery disease or risk factors for ischemic heart disease may be candidates for perioperative β-blockade. If initiation of β-blockers is indicated in the preoperative setting, treatment ideally should start weeks before elective surgery and should be titrated to a target heart rate of 60 to 80 beats/minute. Adverse effects of β-blocker initiation too close to the time of surgery include the risk of stroke, hypotension, and death. For patients with limited cardiac risk factors, rapid initiation of β-blockers in the acute preoperative setting is not indicated.

The AGS Beers Criteria for Potentially Inappropriate Medication Use is particularly relevant to elderly patients at risk for polypharmacy. The latest guidelines (updated in 2015) serve as a reference to check for medications with high-risk adverse effect profiles, common drug-drug interactions, impaired renal and/or hepatic clearance, perioperative sedation, and a predisposition to delirium.[20] Some of the medications, such as benzodiazepines, are categorically contraindicated because they have been demonstrated to increase risk of cognitive impairment, delirium, falls, and other adverse outcomes in older adults.

Functional Status and Frailty

Elderly patients can be impaired in their performance of tasks necessary for independent living. These functional limitations are associated with perioperative complications, failure to rescue, increased length of stay, discharge to facilities other than home, and increased postoperative mortality even after procedures considered to be minor.[21,22] The association between functional dependence and postoperative mortality is present in patients over 60 but is magnified in patients over 80.[23] A simple way to obtain a broad sense of functional dependence is to inquire about a history of falls or to use the widely recognized and validated operational definition based on patient shrinkage, weakness, exhaustion, low physical activity, and walking slowness. More detailed instruments for scoring functional status include the Activities of Daily Living and Instrumental Activities of Daily Living, which describe the ability to perform basic and higher-level functions, respectively (Table 19.6).

The social and family support systems surrounding the patient are intimately interwoven with the functional level of the geriatric patient. The living situation of the patient—independent, with family, in assisted living, or with a neighboring support structure—has far-reaching implications not only for their overall health but also as indicators of postoperative disposition and recovery. Identification and incorporation of the patients' living situation and support system into perioperative decision-making are vital to successful patient-centered recovery processes and management of expectations as well as establishing goals of care and any associated limits.

Series reporting on surgical outcomes of octogenarians and nonagenarians have shown that age is often an inaccurate independent marker for surgical risk. A more accurate predictor is frailty. Although no single definition of frailty exists, the AGS suggests that frailty is a syndrome composed of decreased physiologic reserve and a combination of weakness, fatigue, weight loss, decreased balance, low physical activity, slowed motor processing, social withdrawal, cognitive changes, and vulnerability to stressors. The impact of frailty on postoperative outcomes cannot be overstated. Frailty is associated with major complications and early postoperative mortality for cardiothoracic, orthopedic, otolaryngologic, and elective cancer operations. In a large ACS NSQIP study, the preoperative frailty index was more strongly associated with postoperative cardiac arrest and death than ASA class or history of MI.[24]

Frailty can be measured using exhaustive, multidimensional scales such as the CGA or more pragmatic tests such as the Timed Up & Go (TUG) test, which measures functional mobility.[25] In a comparison of four frailty scales to predict postoperative outcomes of cardiac surgery, gait speed outperformed several more extensive scales in predicting mortality or major morbidity.[26] As the most pervasive gait speed measure, TUG is calculated by measuring the time it takes for a patient to rise from a chair, walk 3 meters, turn, and return to a sitting position in the same chair (Fig. 19.3). In a multi-institutional study of patients undergoing minor and major elective operations for solid malignancies, TUG time >20 seconds was associated with a 50% risk of major complications among patients older than 70, compared with 14% for patients with TUG ≤20 seconds.[27]

Although the physical function domain of frailty may be the easiest and most objective to measure, more comprehensive scales such as CGA may produce more actionable results that can improve optimization in the preoperative setting for elective procedures.

Patient Counseling

Integrated into the process of informed consent is clear communication between physician and patient regarding the patient's individualized goals of treatment. The patient must have clear and

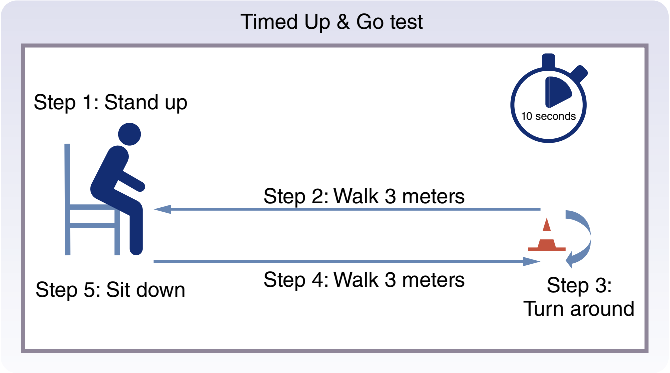

FIGURE 19.3 Timed Up & Go test. (Adapted from www.frailtytoolkit.org.)

realistic expectations regarding the likely treatment course and any potential complications. In the case of older patients, conducting this discussion in the presence of the patient's anticipated postoperative support system—including spouse, adult children, or home nurse—can help ensure that both the patient and the support system are informed regarding necessary postoperative care. This is even more vital if the patient has any cognitive impairment. Regardless of baseline cognitive or functional state, it is strongly recommended that older patients anticipating elective surgery arrange for an advance directive and designate a health-care proxy or surrogate decision-maker. These documents should be prominently featured in the medical chart.

SYSTEMS APPROACH TO PREOPERATIVE EVALUATION

Cardiovascular System

As the US population continues to age, patients with heart disease undergoing elective, noncardiac surgery will increase. Perioperative cardiac complications are associated with morbidity, mortality, and cost. However, preoperative cardiac intervention to reduce the risk of noncardiac surgery is rarely needed, except when such an intervention is indicated for the management of a patient's baseline condition. In the preoperative setting, the goal of cardiology evaluation (if indicated) is not to provide medical "clearance," but rather to provide information regarding the patient's cardiac risk profile and the management options for this risk. The overarching principle of preoperative cardiovascular evaluation is to obtain supplemental testing only when these tests have a reasonable likelihood of changing management. These changes may involve delaying the operation, preoperative revascularization, medical optimization, modifying perioperative monitoring, or referral to a specialty care center.

The ACC and AHA published updated collaborative guidelines regarding perioperative cardiac risk in 2014.[28] In general, for patients with a low risk (<1%) of major adverse cardiac events (MACEs), there is no need for additional testing.

1. High risk category: Associated with cardiac morbidity rates greater than 5%. Examples include aortic and peripheral vascular surgery. Endovascular surgery is included in this category.
2. Intermediate-risk surgery: Cardiac morbidity rates range from 1% to 5%. Examples include abdominal and thoracic procedures, carotid endarterectomy, orthopedic surgery, and head and neck surgery.
3. Low-risk surgery: Cardiac morbidity rates are generally less than 1%. Examples include endoscopic, superficial soft tissue, cataract, breast, and ambulatory operations.

Risk Prediction Scales/Indices

Numerous published tools measure patients' risk of perioperative cardiac morbidity. The most pervasive—and the instrument cited by the 2014 ACC/AHA Guideline on Perioperative Cardiovascular Evaluation and Management of Patients Undergoing Noncardiac Surgery—is the Revised Cardiac Risk Index (RCRI). Originally published in 1999 by Lee and colleagues, the RCRI assigns 1 point to each of the six preoperative risk factors[29] (Table 19.7). Patients with zero, one, two, or more factors are assigned to classes I, II, III, or IV, respectively. The RCRI has moderate discriminatory power between patients at low versus high risk for cardiac complications; its primary advantage is its ease of implementation and relatively objective criteria. The ACC/AHA guidelines also endorse using the ACS NSQIP risk calculator as an alternative or supplement to the RCRI.

Preoperative Testing (Electrocardiogram, Echocardiogram, Stress Test, Angiography)

For patients at low risk for perioperative cardiac complications based on surgical and clinical risk factors, no further testing is indicated before surgery. For patients with known risk factors for coronary artery disease, the ACC/AHA 2014 guidelines provide a useful stepwise approach to further preoperative testing[28] (Fig. 19.4). First, the surgeon determines the urgency of the operation and identifies patient cardiac risk factors or known coronary artery disease. Any emergent operation should proceed, using patient risk factors to guide perioperative monitoring and management. Second, in cases of urgent or elective surgery, the patient should be assessed for acute coronary syndrome and, if suspected, referred for cardiology evaluation as appropriate. An important component of this assessment is an estimation of patient functional capacity, classically measured in metabolic equivalents (METs). An extensive collection of METs for common activities has been compiled by Ainsworth and colleagues.[30] Representative examples are listed in Table 19.8. ACC/ACH guidelines recommend that patients with METs ≥4 without symptoms of cardiac disease proceed with elective or urgent operation. Third, in the absence of acute coronary syndrome, additional testing is pursued based on the combined clinical and surgical risk factors listed earlier, taking into account baseline functional capacity. Any patient undergoing a low-risk operation—regardless of clinical risk factors even with functional capacity <4 METs—has a low risk for cardiac complication and does not require further testing.

For patients undergoing an operation that is not low risk, a 12-lead electrocardiogram (ECG) is indicated for patients with known coronary disease, arrhythmia, peripheral artery disease, and cerebrovascular disease. Even for asymptomatic patients, electrocardiogram may be considered, except for those undergoing a low-risk operation. Assessment of left ventricular function through echocardiography is reasonable for patients with dyspnea of unknown origin or progressive heart failure. For patients with known left ventricular dysfunction, preoperative echocardiogram should be considered if there has not been an assessment within 1 year preceding surgery or they have a decrement in functional status or change in symptoms. Exercise testing with cardiac imaging may be indicated for patients with elevated risk and poor (<4 METs) or unknown functional capacity if patients have three or more risk factors. Patients fitting these criteria who are unable to complete exercise testing may be referred for pharmacologic stress testing, either through dobutamine stress echocardiography or stress myocardial perfusion imaging.[28] Importantly, all of the

aforementioned tests should be pursued only if there is a realistic likelihood that the obtained data could change management.

Surgery After Coronary Revascularization

In general, coronary revascularization for the exclusive purpose of reducing perioperative cardiac risk is not indicated. Revascularization is only indicated before noncardiac surgery if it is recommended by baseline clinical practice guidelines. If percutaneous coronary intervention (PCI) is indicated in the preoperative setting, balloon angioplasty, bare-metal stent (BMS) implantation, or drug-eluting stent(s) (DES) revascularization may be considered based on preoperative stress imaging and coronary angiographic findings. For patients considering elective noncardiac surgery after recent coronary revascularization, surgery should be delayed a minimum of 14 days after balloon angioplasty and 30 days after BMS implantation.[28] Ideally, elective surgery should be delayed for 6 months after implantation of DESs because of the need for dual antiplatelet therapy. An operation with interruption of dual antiplatelet therapy can be considered after 90 days following DES placement if risk of further surgical delay exceeds the risk of stent thrombosis and ischemia. As with any high-risk patient care situation, direct communication between a surgeon and medical subspecialist—in this instance a cardiologist—is imperative.

Other High-Risk Cardiac Patients

Patients with moderate to severe left-sided heart failure, right-sided heart failure and/or significant pulmonary hypertension (pulmonary artery pressure >25 mm Hg), or severe aortic stenosis (aortic valve area <1 cm^2) are at significantly increased risk of death. Elective or urgent operations in patients with these cardiac comorbidities require a multidisciplinary approach and risk-benefit discussion. Although optimization with medical management (e.g., diuretics) or preoperative valve replacement (traditional or transcatheter) might be feasible in some patients, the risk of elective operations in patients for whom cardiac function cannot be improved can exceed the potential benefit of the operation, and nonoperative management strategies should be considered.

Perioperative Cardiovascular Medications

Robust evidence supports the use of perioperative β-blockade to reduce cardiac events; however, there is a paucity of data indicating improvement in surgical mortality. Conversely, β-blockers are associated with bradycardia, hypotension, and stroke. As such, the ACC/AHA guidelines recommend that β-blockers be continued in the perioperative setting for patients for whom it is an established preoperative medication. For patients with intermediate- or high-risk myocardial ischemia and for patients with three or more RCRI risk factors, perioperative β-blockers can be initiated. However, it is important to start treatment more than 1 day before surgery.[28] Patients taking statins at baseline should continue therapy in the perioperative setting. Those who do not take statins but are about to undergo high-risk surgery—including vascular surgery—should start statin treatment.

Management of antiplatelet therapy in the early period after coronary revascularization should be determined by consensus between the surgeon, the anesthesiologist, and the cardiologist. In general, perioperative use of aspirin monotherapy is safe in the vast majority of patients who require general and cardiovascular operations. Unless surgical bleeding risk outweighs the risk of stent thrombosis, dual antiplatelet therapy should be continued within the first 4 weeks after BMS and 6 months after DES placement. If discontinuation of a $P2Y_{12}$ inhibitor (clopidogrel, prasugrel, ticagrelor) is necessary to prevent surgical bleeding, it is recommended that aspirin be continued if possible and that the $P2Y_{12}$ inhibitor be restarted as soon as possible after the operation.

Pulmonary System

Postoperative pulmonary complications occur in approximately 6% of patients after major abdominal operations and are associated with increased mortality, ICU admission, and a greater length of stay. This risk is increased in patients diagnosed with COVID-19 within 4 weeks of an operation. This increased risk decreases significantly between 4 and 8 weeks after diagnosis, and after 8 weeks the risk is equivalent to patients without COVID.[31] Although the exact definition of pulmonary complication varies, the major categories include pneumonia/infection, respiratory failure requiring prolonged ventilation, exacerbation of chronic obstructive pulmonary disease (COPD), and lobar/parenchymal collapse with or without associated effusion. The American College of Physicians (ACP) provided guidelines for pulmonary complication risk assessment in 2006 based on a systematic review of patient- and procedure-related preoperative risk factors.[32] The Assess Respiratory Risk in Surgical Patients in Catalonia (ARISCAT) study, one of the largest prospective multi-institutional studies on pulmonary complications, supplemented these guidelines in 2010 and proposed an objective scale for risk stratification[33] (Table 19.9).

Broadly, the ACP guidelines indicate that patient-related risk factors for postoperative pulmonary complications include age >50 years, ASA class II or above, functional dependence,

hypoalbuminemia (<3.5 g/dL), COPD, and heart failure. Although COPD is consistently associated with postoperative morbidity, there is no specific level of preoperative pulmonary impairment that precludes nonthoracic surgery. In fact, congestive heart failure—especially when associated with pulmonary hypertension—is a considerably stronger predictor of postoperative pulmonary complications than severe COPD. Active smoking is associated with a moderate increase in risk of postoperative complications, and smoking cessation at least 4 weeks before the operation reduces the risk of complications. Although there is no clear evidence supporting an association between obesity and pulmonary complications per se, both obstructive sleep apnea (OSA) and obesity hypoventilation syndrome—which often complement overweight, metabolic syndrome, and morbid obesity—are associated with pulmonary complications and death.

Procedure-related risk factors that increase the risk of pulmonary complications include vascular surgery, thoracic surgery, abdominal surgery, neurosurgery, general anesthesia, head and neck surgery, procedure duration (>3 hours), and emergency surgery. Pulmonary complications increase in likelihood the closer the surgical incision is in relation to the diaphragm. Because general anesthesia conveys a higher risk of clinically relevant pulmonary complications than regional anesthesia, the latter should be considered when possible for patients with multiple patient-related risk factors.

Appropriate preoperative pulmonary evaluation begins with a thorough history and physical examination focusing on potential patient-related risk factors. Spirometry is indicated for physiologic assessment and residual lung volume estimation preceding pulmonary resection and for patients suspected of having undiagnosed COPD. Spirometry and chest radiography should be considered in patients with a preexisting diagnosis of COPD or asthma if history and physical examination cannot determine whether the patient is at their optimal baseline physiology. However, these tests should not be used in routine screening for low-risk patients or if the results of tests will not affect clinical decision-making. There is no prohibitive spirometric threshold below which nonthoracic surgery is strictly contraindicated. Routine chest radiography may be indicated in patients >50 years of age who are undergoing high-risk surgery. Chest radiography is used in some patients for preoperative staging in preparation for resection of abdominal and gastrointestinal neoplasms, though computed tomography (CT) has supplanted x-ray in many instances as the imaging modality of choice for staging most malignancies. Pulse oxygen saturation is a risk factor within the ARISCAT index, and its low resource utilization allows for routine screening.

There are numerous predictive indices for pulmonary complications. The most frequently cited include the Arozullah index, the ARISCAT index, and the Gupta respiratory failure calculators. The ARISCAT index is the simplest to use, featuring seven readily available preoperative predictors in a simple scoring system[33] (see Table 19.9). The disadvantage of the ARISCAT index is that it may overestimate postoperative complication rate because its complication definition includes minor morbidities such as small radiographic effusions and bronchospasm/wheezing, and the current calibration of the model may not be optimal for use in homogeneous populations and may require recalibration.[34] The Arozullah index, derived from a veteran population, specifically targets postoperative respiratory failure. More cumbersome for routine implementation, it includes more than 12 risk factors, some of which may not be routinely available. More recently, Gupta and colleagues developed risk calculators using the ACS NSQIP dataset with primary outcomes of postoperative respiratory failure and pneumonia[35]; these calculators are available on the web or as a downloadable mobile app.

OSA and obesity hypoventilation syndrome deserve additional consideration. Older age, obesity, and male sex are associated with a higher prevalence of OSA. A simple STOP-BANG questionnaire has been developed to screen patients for OSA and stratify patients into risk categories based on the presence of symptoms. The eight-question scoring tool includes yes/no responses to (1) snoring, (2) daytime tiredness, (3) observation of stopped breathing or interrupted breathing during sleep, (4) high blood pressure, (5) body mass index (BMI) >35, (6) age >50, (7) neck diameter >40 cm, and (8) male sex.[36] Patients with five or more risk factors are considered at high risk for moderate to severe OSA. If an elective operation is planned, these patients should be considered for a sleep study. If positive, they should have preoperative continuous positive airway pressure (CPAP) machine fitting and optimization. Patients requiring urgent or emergent operations are managed for OSA in the postoperative setting.

Obesity hypoventilation syndrome is defined as a combination of BMI >30 with awake $PaCO_2$ >45 mm Hg indicative of hypercapnia not primarily related to other causes such as primary lung disease, medication use, or a neurologic disorder. There are no strict guidelines for arterial gas measurements in obese patients, although the highest risk for hypoventilation is in patients with a BMI exceeding 50. The problem of hypoventilation can be exacerbated in these patients during the perioperative period by general anesthesia and opioids. Consideration for postoperative capnography and adherence to OSA screening and postoperative CPAP use can decrease the risk of respiratory failure and death.

Renal System

Patients with chronic renal insufficiency—particularly those on hemodialysis—experience substantially greater perioperative morbidity and mortality than the general population. Patients on dialysis have greater pressor requirements, longer periods of mechanical ventilation, and longer ICU and overall hospital stay. The cause of this elevated risk is a high rate of concurrent cardiac disease, perioperative fluid and electrolyte disturbance, uremia-mediated bleeding diathesis, and poor perioperative blood pressure management. Preoperative measures to accommodate patients with chronic renal insufficiency primarily focus on a thorough assessment of comorbidities, optimizing fluid and electrolyte status, and securing adequate resources for perioperative care.

Chronic kidney disease (CKD) is a consistent predictor of death and cardiac arrest in the perioperative patient. Assessment of associated cardiac risk begins with a thorough history and physical examination, with attention to predictive indices such as the RCRI (see earlier). Because renal insufficiency is a risk factor within the RCRI, preoperative testing for patients with renal insufficiency broadly follows the guidelines put forth by the ACC/AHA. Patients with stage 1 to 2 chronic renal insufficiency and functional capacity >4 METs who are undergoing low- or intermediate-risk surgery do not require additional preoperative studies. Patients who have stage 3 to 5 renal insufficiency or are undergoing high-risk surgery should receive additional cardiac evaluation, including electrocardiogram, complete blood count, blood chemistry and electrolytes, and urinalysis. Echocardiography should be done in patients with volume overload despite optimal CKD management to evaluate for concomitant cardiac dysfunction.

For patients on dialysis, preoperative management focuses on fluid and electrolyte optimization and preservation of hemodynamic stability. The ideal timing of preoperative dialysis is the day before the operation or the day of surgery. Dialysis goals should include the achievement of near-normal electrolyte levels and euvolemia, making the patient close to dry weight. Hyperkalemia is a life-threatening complication of renal disease and must be considered preoperatively in all patients with renal insufficiency and addressed during all perioperative stages. A normal potassium level is a prerequisite for patients with CKD being considered for an elective or urgent operation, as intraoperative medications to counteract hyperkalemia are limited, and hyperkalemia can result in intraoperative death. Although some experts recommend increasing the amount of peritoneal dialysis for 1 week before surgery, objective data do not exist regarding this practice. Patients who have recently initiated dialysis may possess residual renal function. This function is critical for solute clearance and fluid balance during the first year on dialysis and confers a long-term survival benefit for dialysis patients. Thus, its preservation during the perioperative period is critical. Although evidence-based research remains inconclusive, holding diuretics, angiotensin-converting enzyme inhibitors, and angiotensin receptor blockers in the perioperative period should be considered because these medications can result in variable hemodynamic changes during and after surgery.[37] Once the patient is stable after the operation, these medications should be resumed early in the postoperative period because they may be associated with long-term preservation of residual glomerular filtration rate.

Chronic renal insufficiency affects hematologic function as well, and chronic anemia is common in this population. After addressing the various etiologies for chronic anemia, erythropoietin or darbepoetin may be started for preoperative optimization.

If the hemoglobin remains below target, the patient may require iron studies and investigation into possible erythropoiesis-stimulating agent (ESA) resistance. Although chronic renal insufficiency does not affect platelet count, uremic platelet dysfunction is common. Desmopressin should be readily available and administered if medical bleeding from platelet dysfunction is encountered. Cryoprecipitate and platelet transfusion can be used if necessary. Intraoperative and postoperative medications must undergo diligent dose adjustment, and nephrotoxic agents—including nonsteroidal antiinflammatory drugs (NSAIDs), aminoglycosides, amphotericin B, and contrast dye—should be avoided if possible in patients with residual renal function.

For all patients with CKD, avoidance of secondary renal insults is vital to the preservation of any residual renal function. Maintenance of adequate intravascular volume and avoidance of hypotension in the intraoperative and early postoperative periods are particularly important. For patients without residual renal function and on dialysis, the use of nephrotoxic medications and agents can be considered.

Hepatobiliary System

Patients with impaired liver function are at elevated risk for surgical- and anesthesia-related complications. A thorough preoperative history and physical examination provide cues in terms of hepatic dysfunction. Acute hepatitis of any etiology (e.g., viral, medication induced, autoimmune, obesity related) requires appropriate diagnosis, evaluation, and management. Chronic liver disease, including fibrosis and cirrhosis, can have a significant impact on patients' operative planning and postoperative outcomes. Risk factors for chronic liver disease evident on history can include social behaviors (e.g., injectable drug use, significant alcohol use, tattoos, history of multiple sexually transmitted diseases), long-term obesity, and familial chronic liver disease. Many of the findings on the review of symptoms (pruritus and other manifestations such as jaundice, ascites, and gynecomastia) and physical examination features (spider telangiectasias, caput medusae, icterus, splenomegaly, and fluid wave) are usually found in patients with long-standing cirrhosis. For patients without evidence of liver dysfunction on history and physical examination, routine preoperative testing for liver function in the setting of nonhepatobiliary surgery has low predictive value and is not recommended.

Surgical risk in patients with hepatic disease may be stratified by clinical scenarios and objective measures. Contraindications to elective surgery include acute or fulminant hepatitis and alcoholic hepatitis. Patients with fibrosis without cirrhosis can usually tolerate elective surgery with low morbidity; however, anesthetic agent modifications might be necessary. Common anesthetics, such as propofol, ketamine, etomidate, benzodiazepines, and opioids, undergo hepatic metabolism. Nondepolarizing neuromuscular blockers also pose a pharmacodynamic challenge because patients with liver disease frequently have greater volume of distribution but a slower drug elimination rate. Cirrhosis is associated with increased mortality across all types of major elective surgery. But this risk may vary depending on the type of procedure, with odds ratios ranging from 3.4 for cholecystectomy to 8.0 for CABG.[38]

The three most common objective measures of surgical risk in patients with cirrhosis are the Child-Turcotte-Pugh (CTP) score, the MELD score, and residual liver volume. The CTP classification (Table 19.10) of cirrhosis was popularized in the 1980s, given the ease of calculation and correlation with perioperative mortality after abdominal surgery. Originally proposed by Child and Turcotte, this score estimated the procedural risk for portosystemic shunting for variceal bleeding. Later, the score was modified by Pugh and colleagues to include prothrombin time (PT) and exclude nutritional status. A CTP score of 5 to 6 is considered class A (well compensated), 7 to 9 is considered class B (significant compromise), and 10 to 15 is considered class C (decompensated). As surgical technique and perioperative care improved over recent years—particularly with the popularization of laparoscopic and robotic surgery—mortality rates for each CTP class have decreased. Although outcomes vary by type of procedure, broad estimates of mortality for abdominal operations are 10%, 20%, and 60% for CTP A, B, and C, respectively.[39]

TABLE 19.10 Modified Child-Turcotte-Pugh Scoring System With Historical Associated Survival Statistics

	POINTS		
VARIABLES	**1**	**2**	**3**
Encephalopathy	None	Grade 1–2	Grade 3–4
Ascites	Absent	Slight	Moderate
Serum albumin (g/L)	>3.5	2.8–3.5	<2.8
International normalized ratio	<1.7	1.7–2.3	>2.3
Total bilirubin (mg/dL)	<2	2–3	>3
or total bilirubin (mg/dL) in patients with PBC/PSC	<4	4–10	>10
	CLASS A	**CLASS B**	**CLASS C**
Total points	5–6	7–9	10–15
Historical 1-year survival	100%	80%	45%
Historical 2-year survival	85%	60%	35%

PBC, Primary biliary cirrhosis; *PSC,* primary sclerosing cholangitis.

The MELD score is predictive of disease severity and mortality risk in patients with cirrhosis and was originally developed primarily for transplant allocation. The MELD score has gradually supplanted CTP classification for both liver-directed operations and nonhepatic surgical risk stratification. Unlike CTP score, which includes equally weighted subjective components such as encephalopathy and ascites, the MELD score is composed only of objective measures: total bilirubin (mg/dL), creatinine (mg/dL), and international normalized ratio (INR, %) (Table 19.11). Thirty-day mortality ranges relatively linearly with MELD score, with MELD <8 associated with 6% mortality, and MELD >20 associated with a greater than 50% mortality.[40] Despite the creation of a more objective score, the MELD score is unable to accurately predict the risk of mortality in about 15% to 20% of patients with cirrhosis. In 2008, the MELD score was adapted to include the serum sodium to more accurately predict mortality in this patient population. In 2016, the United Network for Organ Sharing (UNOS) adopted the MELD-Na score for deceased donor liver transplant organ allocation. This new policy also accounts for the following MELD exceptions:

- Hepatocellular carcinoma (HCC)
- Hepatopulmonary syndrome
- Portopulmonary hypertension
- Familial amyloid polyneuropathy
- Primary hyperoxaluria
- Cystic fibrosis

TABLE 19.11 MELD-Na Scoring System With Associated Survival Statistics

MELD-Na = MELD + 1.32* (137-Na) - [0.033*MELD * (137-Na)]

MELD SCORE	3-MONTH MORTALITY RISK
<17	<2%
17–20	3%–4%
21–22	7%–10%
23–26	14%–15%
27–31	27%–32%
>32	65%–66%

Note that sodium values less than 125 mmol/L are set to 125, and values greater than 137 mmol/L are set to 137.

- Hilar/perihilar cholangiocarcinoma
- Hepatic artery thrombosis occurring within the initial 14 days after liver transplant

Overall, the predictive utility of both MELD and CTP scores may be greater for urgent than for elective operations. More importantly, appropriate preoperative patient selection and optimization are paramount in patients with cirrhosis selected for an elective surgical procedure.

Common general surgical problems encountered in patients with cirrhosis include abdominal wall hernias and biliary tract disease. Significant and poorly controlled ascites predisposes to hernia development through congenital abdominal wall defects. Emergency hernia repair (for repair of a transabdominal defect with leaking ascites) is associated with higher morbidity and mortality. As such, preoperative management and control or reduction of ascites is paramount for successful hernia repair, long-term durability, and perioperative safety. When hernia repair is pursued, abdominal wall closure with suture (without mesh) is both feasible and safe. Numerous studies demonstrated better outcomes after a laparoscopic approach to cholecystectomy when compared with an open approach in patients with cirrhosis. For all patients with cirrhosis, operative risk increases with higher CPT (B, C) and higher MELD (>18–20). Multidisciplinary risk-benefit analysis is vital in these patients. Patients with decompensated cirrhosis (CPT C; high MELD) awaiting liver transplantation would benefit from hernia repair after transplantation and/or delaying cholecystectomy to the time of liver transplantation.

When considering hepatic resection, residual liver volume is predictive of postoperative morbidity, particularly posthepatectomy liver failure (PHLF). Generally defined as PT >50% of normal (INR >1.7) and serum bilirubin >2.9 mg/dL (50 μmol/L) on postoperative day 5—often referred to as the *50-50 criteria*—PHLF is associated with up to 50% mortality rate.[41] For patients without cirrhosis undergoing hepatic resection, a residual liver volume of 20% is generally considered adequate. This minimum is estimated at 40% for patients with compensated cirrhosis. Residual liver volume is most commonly estimated by CT or MRI volumetry using integrated software, taking into account the proposed resected liver volume and the patient's body surface area.[42] Recently, several equations have been proposed using metrics such as total liver volume, thoracic width, liver height, sex, and patient body weight.

Patients with chronic liver disease should be medically optimized before surgery. Synthetic function should be evaluated through assessment of PT, albumin, and fibrinogen levels. Creatinine and total bilirubin are necessary to complete preoperative MELD risk assessment. However, it is important to note that PT does not directly correlate with bleeding risk in patients with cirrhosis. In fact, patients with cirrhosis and elevated PT/INR can have hypercoagulability.[43] By treating ascites with preoperative diuresis or paracentesis, surgeons may reduce the risk for dehiscence or herniation. Renal function is particularly important in patients with cirrhosis. Clinicians must be mindful that the impaired synthetic function of these patients may artificially lower urea and creatinine synthesis. Finally, malnutrition is common among patients with cirrhosis and is associated with poor perioperative outcomes. Preoperative nutritional supplementation—including replacement of fat-soluble vitamins as indicated—may be indicated for patients with evidence of recent weight loss or hypoalbuminemia.

Hematologic System

Bleeding and thromboembolism are among the most worrisome, and preventable, operative complications. As such, a thorough hematologic history and physical examination are indicated for every patient considered for an operation. This includes evaluation for symptoms of anemia (fatigue, pallor, hematochezia, dyspnea, palpitations), coagulopathy (petechiae, bleeding diathesis, medications), and hypercoagulability (thrombosis, edema). Physical examination should assess for vital signs, hepatomegaly and splenomegaly, lymphadenopathy, skin tone, extremity edema, and rectal bleeding. A thorough reconciliation of baseline medications is critical because antithrombotic medications require careful management in the preoperative setting. Information regarding liver and kidney function also affects risk assessment for bleeding and perioperative VTE prophylaxis.

Anemia

Chronic anemia is one of the most common findings on routine preoperative evaluation. Causes are frequently multimodal, including nutritional deficiency, cancer, renal disease, inflammatory disease, infection, and heritable disorders. The vast majority of blood-borne oxygen is delivered via hemoglobin within red blood cells; therefore, anemia can result in significant compromise in tissue oxygenation. However, given the reserve in oxygen delivery compared with tissue utilization, hemoglobin levels considerably below normal ranges are generally well tolerated by healthy patients. Over time, treatment of chronic and perioperative anemia has gravitated from liberal transfusion protocols to restrictive strategies. This is because of a lack of supporting evidence for liberal blood transfusion practice and the measurable risks associated with blood transfusion (Table 19.12).

Triggers for blood transfusion in the setting of anemia should be individualized based on patient and clinical factors; however, general guidelines can help promote institutional consistency. Based on data from more than 12,000 patients across 31 trials, the AABB (formerly the American Association of Blood Banks) provided updated transfusion guidelines in 2016. For most hemodynamically stable, asymptomatic hospitalized patients, transfusion is not indicated until hemoglobin level is ≤7 g/dL. This includes the critically ill patient population. These recommendations are supported by the Transfusion Requirements in Critical Care (TRICC) trial, which demonstrated no difference in 30-day mortality between restrictive and liberal transfusion protocols in critically ill, euvolemic patients

TABLE 19.12 Approximate Risk per Unit Transfusion of Red Blood Cells (RBCs)

ADVERSE EVENT	APPROXIMATE RISK PER UNIT TRANSFUSION OF RBCS
Febrile reaction	l:60[a]
Transfusion-associated circulatory overload	1:100[b]
Allergic reaction	1:250
Transfusion-related acute lung injury	1:12,000
Hepatitis C virus infection	1:1,149,000
Hepatitis B virus infection	1:1,208,000 to 1:843,000[c]
Human immunodeficiency virus infection	1:1,467,000
Fatal hemolysis	1:1,972,000

[a]Estimated to be 1:91 with prestorage leukoreduction and 1:46 with poststorage leukoreduction.

[b]Estimated risk per recipient rather than unit.

[c]The estimate is variable depending on the length of the infectious period.

with anemia in the intensive care setting. Findings from the TRICC trial were recently corroborated by the Transfusion Requirements in Septic Shock (TRISS) trial in patients with septic shock.[44] Among patients with gastrointestinal bleeding, a restrictive transfusion system is associated with lower 30-day mortality.

Potential exceptions to the 7 g/dL transfusion threshold include patients with cardiovascular disease and those undergoing cardiac surgery, for whom a transfusion threshold of 8 g/dL could be considered. The recent Transfusion Requirements in Cardiac Surgery III (TRICS III) trial found no difference in death, MI, stroke, or renal failure between transfusion thresholds of 7.5 g/dL and 8.5 to 9.5 g/dL in patients undergoing cardiac surgery.[45] For asymptomatic patients with baseline cardiovascular disease, the Functional Outcomes in Cardiovascular Patients Undergoing Surgical Hip Fracture (FOCUS) trial suggests that a transfusion threshold of 8 g/dL is not associated with worse postoperative outcomes when compared with a threshold of 10 g/dL.

Anemia in a patient who is acutely bleeding represents a fundamentally different clinical scenario. In these patients, anemia is more closely associated with hypovolemic shock, and rapid hemodynamic instability often makes laboratory-based transfusion protocols unrealistic. For hemodynamically stable patients, a restrictive transfusion system may be reasonable. However, for patients with ongoing bleeding, hemodynamic instability, or massive trauma, empiric blood transfusion and institutional massive transfusion protocols may be lifesaving.

Inherited Coagulopathy

Routine preoperative laboratory screening for bleeding diatheses is discouraged; workup should be guided by questions that assess bleeding risk. The surgeon should elicit a history of frequent nosebleeds, menorrhagia, intraarticular bleeding, and hereditary diseases. Common comorbid conditions that increase bleeding risk include chronic renal or hepatic insufficiency. Prior experiences with invasive procedures and current anticoagulation and antiplatelet medications should be assessed. On physical examination, epistaxis, gingival bleeding, and cutaneous petechiae are suggestive of platelet or collagen disorders. Hemarthrosis, deep hematomas, and large, palpable ecchymoses may indicate factor deficiency. Because of the relatively low incidence of major bleeding in common general surgery operations, studies addressing the value of routine preoperative hemostatic testing are often inadequately powered. If a patient's history and physical examination indicate an increased risk for bleeding, initial laboratory tests should include a complete blood count comprising platelet count, PT with INR, activated partial thromboplastin time (aPTT), creatinine, and hepatic function panel. Patients with signs of hereditary bleeding disorders should be referred for preoperative hematologic consultation.

When considering the diagnostic approach to hereditary bleeding disorders, the first separation is between disorders of coagulation and those of platelets and vascular integrity. If the workup includes a normal PT/INR and aPTT, thrombocytopenia or platelet dysfunction should be suspected. Spontaneous bleeding generally does not occur unless the platelet count is below 30,000/μL. Inherited disorders in platelet function or storage include von Willebrand disease (vWD; the most common), Bernard-Soulier syndrome, and Glanzmann thrombasthenia. Acquired causes of platelet dysfunction include cirrhosis, myelodysplastic syndromes, uremia, and pharmacologic impacts of aspirin, $P2Y_{12}$ inhibitors, and NSAIDs. A normal PT/INR and aPTT do not rule out coagulopathies outside the measured pathways of these two tests (i.e., factor XIII deficiency) or vascular disorders (inherited and acquired connective tissue disorders, small vessel vasculitis).

Causes of isolated prolongation of aPTT include deficiencies in factors VIII (hemophilia A), IX (hemophilia B), and XI. Hemophilia A and B are by far the most common, and both are X-linked recessive disorders. Isolated prolonged PT, in the absence of pharmacologic contributors or cirrhosis, is indicative of the relatively rare factor VII deficiency. Abnormal results on both PT and aPTT usually indicate a defect in the common coagulation pathway, composed of factors II (prothrombin), V, and X and fibrinogen. Inherited disorders of the common pathway are rare; an extensive investigation into acquired causes is likely to indicate contributors such as vitamin K deficiency, supratherapeutic warfarin, hepatic insufficiency, or disseminated intravascular coagulation. A broad summary of the screening approach to bleeding disorders is provided in Fig. 19.5.

Institutional protocols for perioperative management in patients with inherited bleeding disorders should be a collaboration between hematologists, anesthesiologists, and surgeons. These protocols vary widely because of differences in available laboratory resources and treatments. However, a few guiding principles are relevant in all scenarios. Elective operations for patients with bleeding disorders should be planned with multidisciplinary input to ensure the availability of all laboratory and therapeutic resources in the postoperative period. Multiple avenues of intraoperative venous access should be available for accurate blood sampling away from infusion sites. Perioperative analgesia should not include medications with antiplatelet effects such as aspirin and NSAIDs.

Preoperative treatment for hemophilia A depends on disease severity. Mild phenotypes (factor VIII >5%) respond well to Desmopressin (DDAVP) given the day of surgery, which will raise factor VIII levels up to fivefold within 90 minutes. After administration, factor VIII levels should be measured in the preoperative and postoperative setting, and DDAVP may be redosed on a daily or twice-daily basis as needed. Appropriate attention should be paid

to fluid retention because hyponatremia can be a serious complication of DDAVP, particularly in elderly patients. Because factor IX does not respond to DDAVP, even mild forms of hemophilia B require factor replacement both before and after major surgery to maintain appropriate levels. For both disorders, severe phenotypes should be treated with administration of factor concentrates in the immediate preoperative setting, within 10 to 20 minutes of incision.[46] Reducing the need for repeat dosing of factor concentrates minimizes the likelihood of inhibitor development. Up to 25% of patients with severe hemophilia A will ultimately develop inhibiting antibodies to factor VIII. Inhibitors reduce effectiveness of factor replacement therapy. For patients who have had multiple prior treatments with factor replacement, preoperative inhibitor screening should be performed a week before surgery. The presence of inhibitors indicates the need for procoagulant agents that can bypass the intrinsic pathway, such as activated recombinant factor VII or activated prothrombin complex concentrate.

Von Willebrand factor (vWF) mediates platelet adhesion to collagen and other platelets. It is the carrier protein for factor VIII. vWD, a disorder of vWF, is subdivided into three broad types. Type 1 is a partial deficiency of vWF. It is the most common version and responds well to DDAVP administered 1 hour before incision. Because vWF is an acute-phase reactant, levels generally remain elevated postoperatively. Type 2 vWD comprises a variety of qualitative defects in vWF that can result in decreased binding of factor VIII and disorders in platelet function (2A, 2B, and 2M). Although DDAVP may induce a partial response in patients with types 2A and 2M vWD, it is contraindicated in type 2B because it may cause thrombocytopenia.[46] Type 3 vWD is a complete or near-complete deficiency in vWF and universally does not respond to DDAVP. For all patients with type 3 vWD and most patients with type 2 disease, vWF concentrate is the treatment of choice. Preoperative measurement of factor levels should be obtained before elective surgery, and minimum target trough levels should be tailored to the type of surgery (Table 19.13).

Antiplatelet Therapies

The 2016 ACC/AHA guidelines recommend an individualized approach to weighing risks of surgical bleeding and cardiac risk among patients on chronic antiplatelet therapy.[28] Patients who are on chronic low-dose aspirin therapy but who have not previously undergone coronary stenting should continue aspirin in the perioperative setting if the bleeding risk is low. In general, perioperative use of aspirin antiplatelet monotherapy is safe in most patients who require general and cardiovascular operations. Elective operations that require discontinuation of dual antiplatelet therapy (e.g., aspirin and clopidogrel) should be avoided within 30 days after BMS implantation or within 6 months after DES implantation. Surgical delay after DES implantation may be reduced to 3 months if the risk of delay is greater than the risk of stent thrombosis. For urgent operations within 4 weeks after BMS or DES implantation, dual antiplatelet therapy should be continued unless there is a significant risk for life-threatening surgical bleeding. If there is a surgical need to discontinue $P2Y_{12}$ inhibitor

therapy during this time, aspirin should be continued and the $P2Y_{12}$ inhibitor should be restarted as soon as possible postoperatively. A summarization of the ACC/AHA recommendations for antiplatelet therapy in the setting of recent coronary stenting is shown in Fig. 19.6. Importantly, for patients not previously on aspirin therapy, initiation of aspirin for perioperative cardiac risk reduction is not supported by current evidence. The landmark Perioperative Ischemic Evaluation 2 (POISE-2) trial concluded that administration of aspirin in the perioperative setting has no impact on death or MI and increases the risk of major bleeding.[47]

Anticoagulation

Consideration of perioperative management of anticoagulants balances the risk of bleeding against that of thromboembolic complications. In addition to determining the duration of anticoagulant interruption, clinicians must decide whether a bridging agent is indicated. Patients at exceptionally high risk for thromboembolic complications (i.e., recent ischemic stroke, inadequate anticoagulation in the setting of atrial fibrillation with CHA_2DS_2-VASc >1 for males and >2 for females) should not undergo elective operations until the clotting risk is optimized. Operations with low risk of bleeding—such as many cutaneous operations—can proceed without interruption of chronic anticoagulation. In the case of cardiac interventions for arrhythmia, it may be undesirable to interrupt anticoagulation even in the perioperative setting. The American College of Chest Physicians Evidence-Based Clinical Practice Guidelines (2012) represent the most widely accepted recommendations for perioperative antithrombotic management.[48]

Clinicians should consider the pharmacokinetics of anticoagulants to keep interruptions in chronic anticoagulation as short as possible. Warfarin, with a half-life of 36 to 42 hours, should be discontinued 5 days before elective operations, which eliminates the need for any additional preoperative PT/INR evaluation. A preoperative INR done 1 to 2 days before the day of surgery is reasonable for a patient who discontinued warfarin <5 days before their procedure or if their recent INR is >4.5. If the INR remains above 1.5, oral vitamin K or fresh frozen plasma (FFP) can be administered preoperatively depending on the extent of coagulopathy and operative planning. Because it usually takes 4 to 5 days for warfarin to attain therapeutic anticoagulation levels, restarting warfarin within 24 hours after surgery will result in an average of 8 to 9 days of subtherapeutic anticoagulation during the perioperative period. For this reason, bridging anticoagulation should be considered for patients at very high risk of thromboembolism.[48] These patients include those with a recent ischemic stroke, acute arterial embolism, a mechanical heart valve, CHA_2DS_2-VASc >7 or 8, or VTE at high risk for thromboembolism. Previous guidelines recommended bridging for high-risk atrial fibrillation as well. However, results from the double-blind placebo-controlled BRIDGE trial concluded that forgoing bridging with low-molecular-weight heparin (LMWH) in this setting does not increase risk for arterial thromboembolism and decreases the risk of major bleeding.[49] When used in the setting of bridging treatment, unfractionated heparin should be stopped 4 to 6 hours before surgery, whereas LMWH should be stopped 24 hours before surgery. For operations with high bleeding risk, therapeutic-dose LMWH should be resumed 48 to 72 hours postoperatively; for minor operations with a low bleeding risk, LMWH can usually be resumed after 24 hours postoperatively.

Oral Direct Thrombin and Factor Xa Inhibitors

Modern oral anticoagulant agents include the direct thrombin inhibitor dabigatran (Pradaxa) and direct factor Xa inhibitors rivaroxaban (Xarelto), apixaban (Eliquis), and edoxaban (Savaysa). These agents possess several advantages over the traditional inhibitor of vitamin K–dependent coagulation factors: warfarin. Namely, they offer more rapid onset (less than 4 hours) and shorter half-life, allowing a shorter period of interruption in the perioperative setting. Routine long-term laboratory testing for drug levels is not required. However, perioperative management of these agents requires knowledge of basic pharmacokinetics and options for reversal.[50] A summary of common oral anticoagulants is provided in Table 19.14.

The 2020 PAUSE trial evaluated a standardized approach to direct oral anticoagulant (DOAC) management for high-risk and low-risk procedures.[51] Dabigatran was approved by the US Food and Drug Administration (FDA) for stroke prevention in atrial fibrillation in 2010. Its clearance is renal, with a half-life of 12 to 17 hours. For patients with normal renal function who are anticipating major surgery or with impaired kidney function, dabigatran should be held for 48 hours before surgery and resumed

the day after surgery for low-risk procedures and 2 days after for high-risk procedures or for patients with impaired kidney function. Dabigatran can be monitored using dilute thrombin time or liquid chromatography–mass spectrometry (LC-MS/MS) drug level. In 2015, the FDA approved idarucizumab (Praxbind) as a specific reversal agent for dabigatran. Rapid reversal is achieved with a single 5-g IV dose.

Rivaroxaban, apixaban, and edoxaban are direct factor Xa inhibitors; they can be monitored using a chromogenic anti-Xa assay or LC-MS/MS. Clearance includes renal excretion in urine and hepatic metabolism via CYP3A4. As such, drug interactions are common with cytochrome P450 inhibitors (e.g., ketoconazole, amiodarone, selective serotonin reuptake inhibitors [SSRIs], cimetidine) and inducers (e.g., carbamazepine, phenytoin, rifampin). In addition, factor Xa inhibitors are substrates of P-glycoprotein efflux transporters. Therefore, drugs that inhibit both CYP3A4 and P-glycoprotein—the classic example is ketoconazole—can cause profound amplification of anticoagulation effects. Oral Xa inhibitors have rapid onset (2–4 hours) and relatively short half-lives, allowing for short periods of interruption perioperatively. They should be stopped 48 hours before surgery for high-risk operations and 24 hours before surgery for low-risk operations and resumed 1 to 2 days postoperatively.[51] In 2018, the FDA approved andexanet alpha (Andexxa) as a targeted reversal agent for oral factor Xa inhibitors. Administration involves an initial bolus of 400 to 800 mg, followed by a continuous infusion.

Endocrine System

Endocrine comorbidities can significantly influence perioperative physiology and are important to consider during preoperative

TABLE 19.14 **Oral Anticoagulants**

DRUG	TRADE NAME	MECHANISM	MONITORING	CLEARANCE	ONSET	HALF-LIFE (H)	PREOP HOLD	POSTOP RESUME	REVERSAL
Warfarin	Coumadin	Inhibitor of vitamin K–dependent factor synthesis	PT/INR	Hepatic (CYP1A2, CYP3A4)	>4 days	36–42	5 days	12–24 h	PCC, FFP, vitamin K

evaluation. Although diabetes mellitus is the most common endocrinopathy, physiologic imbalances of thyroid and adrenocortical systems, as well as endogenous hormone oversecretion by functional neoplasms, are critical to diagnose and manage during the perioperative period. Management of functional endocrinopathies are briefly addressed in this section and discussed further in disease-specific chapters.

Diabetes Mellitus

Approximately 11% of the population of the United States has diabetes mellitus. Chronic sequelae are multifactorial and affect cardiovascular, renal, and neurologic systems. Preoperative evaluation should focus on pertinent physical examination and laboratory findings. These include ECG and electrolyte studies to evaluate for the long-term effects of poor glycemic control on the myocardium, cardiac conductivity, and renal function. Hemoglobin A1c helps evaluate the efficacy of glycemic control.

Medical management of diabetes mellitus continues to evolve. A number of short-, intermediate-, and long-acting insulin formulations are commercially available. In general, long-acting insulin (glargine or detemir) should be administered as scheduled during the perioperative period. Intermediate-acting insulin (NPH, zinc insulin, extended zinc insulin) should be administered at half the dose on the morning of surgery and resumed at the normal dose once a normal diet has been resumed. Short-acting insulins (regular, lispro, glulisine, and aspart) are generally held and not administered during the morning of surgery. Premixed or proportional combinations of intermediate-acting with short-acting insulins such as 70/30 or 50/50 should generally be reduced by 20% the night before and by 50% on the morning of surgery. Insulin pumps should be set to the basal infusion rate and reprogrammed to regular settings once a normal diet has been established. Inpatient endocrinology consultation is frequently helpful in the management of patients with complex insulin regimens or poor glycemic control.

Perioperative management of oral hypoglycemics has also evolved. In general, sulfonylureas (e.g., glyburide, glipizide, glimepiride, and other single-agent or combination sulfonylureas) and metformin are withheld the day of surgery. DPP-4 inhibitors (gliptins) typically are administered the morning of surgery. SGLT2 inhibitors should typically be held 3 to 4 days before surgery because of the high risk of euglycemic diabetic ketoacidosis, hypovolemia, and urinary tract infection in the perioperative setting. GLP-1 agonists should be held for 1 week before surgery.

Metabolic Syndrome

Metabolic syndrome, also referred to as *insulin resistance syndrome* or *syndrome X,* is a complex condition characterized by a cluster of risk factors and the presence of any three of the traits listed here. It affects approximately 22% of the US population[52]:

- Abdominal obesity with a waist circumference ≥102 cm (40 in) in males and ≥88 cm (35 in) in females
- Fasting blood glucose >100 mg/dL or on medications for elevated blood glucose
- Hypertension with systolic blood pressure >130/85 mm Hg or on hypertensive medications
- Serum high-density lipoprotein (HDL) <40 mg/dL in males or <50 mg/dL in females
- Serum triglycerides >150 mg/dL or use of a statin for elevated triglycerides

Individuals with metabolic syndrome are at increased perioperative risk, such as delayed wound healing, postoperative infections, and cardiovascular complications. These patients require perioperative assessment involving meticulous blood pressure control and glycemic management.

Thyroid Disease

Thyroid function panel and measurement of thyroid-stimulating hormone readily identify patients with thyroid-related endocrinopathies. Patients with hyperthyroidism typically are suppressed preoperatively before thyroid surgery. Nonthyroid elective operations should be delayed until hyperthyroidism is addressed. Hypothyroidism is an indolent chronic disease, and patients with asymptomatic hypothyroidism can be started on thyroid replacement hormone at any time during perioperative care. Symptomatic hypothyroidism is manifested by a decrease in metabolism (e.g., fatigue, weight gain, heat dysregulation). Symptomatic hypothyroidism can affect electrolyte regulation, coagulation, myocardial conduction, and other metabolic pathways; elective operations in patients with symptomatic hypothyroidism should be delayed until hypothyroidism is medically corrected.

Adrenocortical System

Patients with functional adrenal neoplasms, including pheochromocytoma and functional adrenocortical carcinoma, as well as patients with functional paraganglioma, have an overproduction of catecholamines, which can be life threatening during the perioperative period. The possibility of hormone production should be tested in all patients with adrenal neoplasms, and medical management, including α- and β-adrenergic blockade, should be accomplished before the date of planned operation for those with catecholamine production. Urgent operations without sufficient adrenergic blockade should be avoided given the high risk of morbidity and mortality.

Patients with adrenal insufficiency are treated with glucocorticoid replacement. In addition, approximately 1% of the population of the United States uses glucocorticoids for a multitude of medical conditions including pulmonary, joint, inflammatory, and other diseases. Traditionally, perioperative high-dose steroid replacement has been used in patients using steroids at baseline. However, recent data suggest that additional (high-dose) steroid administration is not necessary in all patients. Patients with low-dose steroid use (prednisone 5 mg/day or dose equivalent) can continue baseline steroid dosing. Patients with higher daily doses of glucocorticoids for 3 weeks or longer can be tested for suppression of the hypothalamic-pituitary axis with a morning cortisol test. Levels below 5 mcg/dL require steroid replacement, and levels >10 mcg/dL can continue their normal dose. Patients with levels between 5 and 10 mcg/dL require further evaluation with a low-dose adrenocorticotropic hormone stimulation test. Lack of adrenal response to exogenous adrenocorticotropic hormone administration is diagnostic for adrenal insufficiency, and administration of a physiologic replacement dose of glucocorticoids is indicated. In lieu of stimulation testing for all patients using >5 mg prednisone (or dose equivalent), consensus guidelines recommend glucocorticoid replacement dependent on the extent of the planned operation (Fig. 19.7).

Neoplastic Endocrinopathies

Several solid organ neoplasms secrete endogenous hormones. Functional pancreatic neoplasms can secrete excess gastrin, insulin, glucagon, vasoactive intestinal peptide, and other rare peptides. Patients with pancreatic neuroendocrine neoplasms and symptoms concerning for endocrinopathy should complete a preoperative evaluation to establish whether they have a functional tumor. Patients with primary pancreatic, bowel, or lung carcinoid can develop serotonin hypersecretion. In general, clinically significant serotonin production by a primary tumor is rare, and symptoms typically develop primarily in patients with liver metastases.

Carcinoid liver metastases can result in significant hypersecretion of serotonin, histamine, prostaglandins, and other metabolites. Common symptoms of carcinoid syndrome are flushing and diarrhea. Urinary excretion of 5-hydroxyindoleacetic acid (5-HIAA) can be diagnostic. Patients with symptomatic clinical and/or pathologic diagnosis of carcinoid liver metastases or nonmetastatic but symptomatic (flushing/diarrhea) neuroendocrine neoplasms should be managed with a somatostatin-analogue (e.g., octreotide, octreotide long-acting repeatable [LAR], lanreotide) to suppress the activity of the endogenous hormone before pursuing any operative intervention. Patients with long-standing carcinoid symptoms should be evaluated for valvular heart disease because they can develop tricuspid regurgitation, pulmonic stenosis, and/or regurgitation. After somatostatin receptor blockade, clinically significant carcinoid heart disease should be operatively addressed before pursuing tumor-directed surgery.

Regimen	Degree of surgical stress	Glucocorticoid regimen
Patients currently on glucocorticoids	Grade I Minor	• Continue daily dose of glucocorticoid • 25 mg of IV hydrocortisone at induction if not able to tolerate PO • Resume oral daily preoperative glucocorticoid regimen
	Grade II Moderate	• Continue daily dose of glucocorticoid • 25-50 mg of hydrocortisone IV at induction • 15-25 mg hydrocortisone every 6 hours until PO is tolerated and hemodynamically stable[a] • Resume oral daily preoperative glucocorticoid regimen
	Grade III Major	• Continue daily dose of glucocorticoid • 50 mg of hydrocortisone IV at induction • 25 mg of hydrocortisone IV every 6 hours on day 1 and until hemodynamically stable, then 15 mg IV every 6 hours until PO is tolerated[a] • Resume oral daily preoperative glucocorticoid regimen
Patients who stopped or plan to stop glucocorticoids before surgery		• Assess HPA axis in patients with intermediate to high risk (see Table 4) • The closer the date of discontinuing glucocorticoids before surgery, the higher the risk of AI • Treat based on the degree of surgical stress in those who have abnormal HPA axis
Adrenal crisis		• 100 mg of hydrocortisone IV (IM if no IV access) • 50 mg every 6 hours until hemodynamically stable and then taper[a] • Taper depending on clinical response-Intravenous fluids (normal saline), dextrose 5% if hypoglycemia

FIGURE 19.7 Perioperative steroid supplementation. Note: These recommendations include the authors' personalized approach to perioperative management in patients with glucocorticoid-induced AI. *AI,* Adrenal insufficiency; *HPA,* hypothalamic-pituitary-adrenal; *IM,* intramuscular; *IV,* intravenous; *PO,* by mouth. [a]Some experts favor continuous glucocorticoid infusion. (From Chen Cardenas SM, Santhanam P, Morris-Wiseman L, Salvatori R, Hamrahian AH. Perioperative evaluation and management of patients on glucocorticoids. *J Endocr Soc.* 2023;7[2]:bvac185.)

Appropriate perioperative octreotide administration is imperative. This typically takes the form of preoperative admission for octreotide infusion or large-dose octreotide administration before anesthetic induction. Intraoperative cardiovascular instability can occur, requiring ongoing high-dose octreotide administration. Intraoperative octreotide infusion is typically weaned in the postoperative period.

Endogenous hypersecretion of antidiuretic hormone causing syndrome of inappropriate secretion of antidiuretic hormone (SIADH) is a rare manifestation of small cell lung cancer and other lung neoplasms. SIADH can also result from neurosurgery (e.g., pituitary surgery) or trauma. Management requires maintenance of euvolemia and appropriate correction of serum sodium.

Nutrition and Obesity

Establishing a patient's nutritional status is a vital component of surgical planning. Physiologic stress from surgery or trauma results in a transient catabolic state, with rapid consumption of energy and protein. Malnutrition in the perioperative setting can have severe consequences, including impaired wound healing, increased likelihood of infection, electrolyte abnormalities, and organ dysfunction. Optimizing perioperative nutrition counterbalances the effects of systemic stress to minimize these negative effects.

Preoperative Nutrition Assessment

During preoperative evaluation, indicators of malnutrition include a history of weight loss and chronic illness. A dietary history should be gathered, including use of nutritional supplements. On physical examination, relevant findings include BMI, temporal wasting, peripheral edema, muscle mass, skin turgor, and presence of petechiae, ecchymoses, or pressure ulcers. Among the many screening tools for malnutrition, the most used is the Nutritional Risk Screen tool (NRS-2002) (Table 19.15). Multiple studies have described associations between greater nutritional risk score as measured by NRS-2002 and postoperative complications, including prolonged hospital length of stay.

Because systemic protein stores are vital for postoperative wound healing, protein status has been a particular focus of preoperative assessment. The most commonly cited serum indicators of protein status are albumin, prealbumin, and transferrin. In a large Veterans Affairs study of noncardiac operations, albumin <3.5 was a strong predictor of early postoperative morbidity and mortality. Given its long half-life (20 days), albumin is generally referenced as an indicator of chronic nutritional status. Prealbumin has a much shorter half-life of 2 days and therefore may reflect more recent nutrition. Importantly, prealbumin and albumin are both negative acute-phase proteins. During acute

TABLE 19.15 Nutritional Risk Screen (NRS-2002) Tool

	IMPAIRED NUTRITIONAL STATUS		SEVERITY OF DISEASE (% INCREASE IN REQUIREMENTS)
Absent **Score 0**	Normal nutritional status	Absent **Score 0**	Normal nutritional requirements
Mild **Score 1**	Weight loss >5% in 3 months or food intake below 50%–75% of normal requirement in preceding week	Mild **Score 1**	Hip fracture[a] Chronic patients, in particular with acute complications: cirrhosis[a], COPD[a] *Chronic hemodialysis, diabetes, oncology*
Moderate **Score 2**	Weight loss >5% in 2 months or BMI 18.5–20.5 + impaired general condition or food intake 25%–60% of normal requirement in preceding week	Moderate **Score 2**	Major abdominal surgery,[a] stroke[a] *Severe pneumonia, hematologic malignancy*
Severe **Score 3**	Weight loss >5% in 1 month (>15% in 3 months) or BMI <18.5 + impaired general condition or food intake 0%–25% of normal requirement in preceding week	Severe **Score 3**	Head injury[a] Bone marrow transplantation[a] *Intensive care patients (APACHE .10)*
Score: Age	+ if >70 years: add 1 to total score above	**Score: Age-adjusted total score**	= **Total score**

Score >3: The patient is nutritionally at risk, and a nutritional care plan should be initiated.
Score <3: Weekly rescreening of the patient. If the patient is scheduled for a major operation, for example, a preventive nutritional care plan is considered to avoid the associated risk status.
NRS-2002 is based on an interpretation of available randomized clinical trials.
[a]Indicates that a trial directly supports the categorization of patients with that diagnosis. Diagnoses shown in *italics* are based on the prototypes given below.
Nutritional risk is defined by the present **nutritional status** and risk of impairment of present status due to **increased requirements** caused by stress metabolism of the clinical condition.
A **nutritional care plan** is indicated in all patients who are:
(1) severely undernourished (score = 3), (2) severely ill (score = 3), (3) moderately undernourished + mildly ill (score 2 + 1), or (4) mildly undernourished + moderately ill (score 1 + 2).
Prototypes for severity of disease. Score = 1: a patient with chronic disease admitted to hospital due to complications. The patient is weak but out of bed regularly. Protein requirement is increased but can be covered by oral diet or supplements in most cases. **Score = 2:** a patient confined to bed due to illness (e.g., following major abdominal surgery). Protein requirement is substantially increased but can be covered, although artificial feeding is required in many cases. **Score = 3**: a patient in intensive care with assisted ventilation, etc. Protein requirement is increased and cannot be covered even by artificial feeding. Protein breakdown and nitrogen loss can be significantly attenuated.
APACHE, Acute physiology and chronic health evaluation; *BMI,* body mass index; *COPD,* chronic obstructive pulmonary disease.

stress and inflammation, increased production of acute-phase proteins results in decreased levels of both albumin and prealbumin, making them less reliable in the perioperative setting. Transferrin has a half-life of 8 to 9 days. In addition to being a negative acute-phase protein, transferrin levels must also take into account serum iron levels.

Nutrition Supplementation

Supplementation of nutrition in the perioperative setting is available via enteral or parental routes. The enteral route offers several advantages and is preferred in most situations. Parenteral nutrition requires special venous access that may be prone to infection. It also confers increased risks of hyperglycemia. Parenteral nutrition frequently lacks immune-bolstering glutamine and omega-3 fatty acids, which support the gastrointestinal tract's important immunologic functions. The intestinal mucosa acts as a physical barrier against infection and produces targeted antibodies including intraluminal immunoglobulin A. During starvation, the mucosa becomes more susceptible to bacterial translocation; enteral feeding helps maintain a healthy intestinal mucosa barrier, decreasing untoward immunologic and translocation effects.

Nutritional prehabilitation before surgery has been the subject of investigation for decades. In 1991, the Veterans Affairs TPN Cooperative randomized patients to preoperative total parenteral nutrition (TPN) or no treatment before noncardiac surgery. The TPN group had more infectious complications overall. However, severely malnourished patients receiving TPN experienced fewer noninfectious complications than controls, suggesting TPN prehabilitation may have a role in select patients.[53] More recent data suggest adopting NRS-2002 as a screening tool and considering parenteral or enteral prehabilitation for patients with severe malnutrition. For patients who are only mildly malnourished, surgery should not be delayed for preoperative nutritional supplementation.

In the postoperative setting, enteral feeding should be initiated early. True contraindications to enteric feeding are few: obstruction, intestinal ischemia, bowel discontinuity, high-output fistulas, and severe malabsorption.[54] Importantly, mechanical ventilation, vasopressor support, and an open abdomen are not strict contraindications to enteral nutrition. Early enteral nutrition (within 24 hours of surgery) is a key component of most enhanced recovery after surgery (ERAS) protocols and may be associated with a reduction in postoperative complications. Awaiting objective signs of bowel function before enteral feeding is not necessary. Among patients undergoing upper gastrointestinal tract resection and reconstruction, early enteral feeding is associated with fewer infections and a shorter hospital length of stay. Only when there is an expectation for more than 7 days of a nonfunctional gastrointestinal tract or longer than 5 to 7 days since the patient demonstrated preoperative malnutrition should a patient be considered for postoperative parenteral nutrition.

Obesity

Obesity is classified as a BMI >30 kg/m^2 and can be further subcategorized into class I with BMI of 30 to 34.9 kg/m^2, class II with BMI of 35 to 39.9 kg/m^2, and class III with BMI >40 kg/m^2. All three classes have varying degrees of surgical complexity and potential complications. These complications include pulmonary, cardiovascular, thromboembolic, and infectious complications. Obese patients experience longer operative times and greater hospital lengths of stay. Many of these outcomes are attributable to comorbidities associated with obesity, including cardiovascular disease, OSA, obesity hypoventilation syndrome, metabolic syndrome, essential hypertension, and diabetes. Consequently, the AHA recommends a preoperative ECG and chest radiography for all patients with BMI >40 who have a risk factor for heart failure or poor exercise tolerance. The STOP-BANG questionnaire is a sensitive screening test for OSA.[36] Routine implementation of this eight-question survey in the obese population can help direct formal polysomnography testing and anticipate difficult airway problems.

PREOPERATIVE CONSIDERATIONS AND CARE PROTOCOLS

Evaluation of the patient in the preoperative setting on the day of surgery provides the surgeon a final opportunity to assess readiness for the operation. Interval changes in clinical condition since the preceding consultation visit should be queried. A reevaluation of preexisting medications, including the timing of the most recent doses, is performed. Appropriate management of baseline anticoagulant and antiplatelet agents, including timing of the last dose, is confirmed. Informed consent is verified again with the patient to ensure that there is an accurate and appropriate understanding of the procedure's objectives and risks. Orders relevant to the immediate perioperative setting are reviewed with the surgery and anesthesiology teams. Important to every operation is a review of the indications for antibiotic prophylaxis and VTE prophylaxis. Perioperative care protocols, such as ERAS protocols and similarly designed pathways, facilitate the standardization of patient care, including preoperative expectations, intraoperative management, and postoperative recovery.

Patient Recovery Pathways

A number of patient recovery pathways have been designed and implemented to standardize perioperative care. The enhanced recovery/ERAS protocols are the best studied and supported in the literature. Initially introduced in the late 1990s and early 2000s, these pathways were initially implemented in colorectal surgery. Strengths include standardization of care in the preoperative setting (e.g., patient education, management of concurrent health conditions, minimizing extended perioperative fasting, routine antiemetic prophylaxis, use of opioid-sparing analgesic techniques), intraoperative setting (e.g., maintenance of normothermia, lung-protective mechanical ventilation, antibiotic prophylaxis, avoidance of volume overload), and postoperative setting (e.g., early ambulation, early enteral feeding, opioid-sparing analgesia, and VTE prophylaxis).[55]

There has been a proliferation of ERAS-type protocols across abdominal general surgery, thoracic surgery, gynecologic surgery, orthopedics, and other surgical subspecialties. The protocols themselves are quite granular, typically enumerating the specific timing of preoperative, intraoperative, and postoperative medications and patient expectations.[56] Patient buy-in and acceptance by multidisciplinary staff, including surgeons, anesthesiologists, and nursing staff, are vital for the success of these patient care pathways. Although pathway implementation frequently demonstrates early improvements in postoperative metrics (e.g., infections, pain scores, length of stay, and others), demonstration of long-term sustained effects have been elusive in some studies. Standardized reporting of compliance and outcomes of such postoperative care protocols has been recommended to understand which elements and/or pathways are best supported by data.

Antibiotic Prophylaxis

SSIs are among the most common causes of nosocomial infection and are associated with increased mortality and postoperative length of stay. SSIs are classified as superficial (involving only the skin or subcutaneous tissue), deep incisional (involving fascia or muscle), and organ space infections. Risk factors for SSI are numerous, including age, obesity, smoking, malnourishment, diabetes, immunosuppression, radiation, and others. Although many risk factors are not modifiable in the immediate perioperative setting, two of the simplest actionable measures that reduce the risk of SSI are the appropriate selection of perioperative antibiotics and the administration of these antibiotics within 1 hour of incision.

The Centers for Disease Control and Prevention (CDC) categorizes wounds into four classes: clean, clean-contaminated, contaminated, and dirty-infected (Table 19.16). Although useful from the standpoint of academic inquiry, recent research has reported limited utility of wound classification as a risk factor for postoperative complications as well as frequent misclassification of surgical incisions.[57]

The Clinical Practice Guidelines for Antimicrobial Prophylaxis in Surgery, a collaborative rubric developed in 2013, provides surgery-specific recommendations for antibiotic prophylaxis[58] (Table 19.17). Selection of appropriate prophylaxis is guided by a few core principles. First, an antimicrobial agent is chosen to target common surgical site pathogens. Clean procedures encounter primarily skin flora, predominantly *Staphylococcus aureus* and coagulase-negative *Staphylococcus*. Coverage for gram-negative rods and enterococci should be added for clean-contaminated cases involving abdominal viscera, the biliary tract, and the heart. Commonly used FDA-approved agents include cefazolin, cefoxitin, cefotetan, and vancomycin. For most operations, cefazolin is an appropriate choice given its low cost, antimicrobial spectrum, and duration of activity. For patients colonized with methicillin-resistant *S. aureus* (MRSA), vancomycin may be an appropriate alternative.

The second consideration in antimicrobial prophylaxis is timing of the first dose. Historical data from the early 1990s suggested that the lowest rate of surgical wound infection was associated with antibiotic administration within 2 hours before incision compared with earlier or postoperative administration. However, the more recent Trial to Reduce Antimicrobial Prophylaxis Errors, a prospective, multicenter trial comparing antimicrobial timing before a variety of operations, reported the lowest infection risk when antibiotics were administered within 30 minutes of incision or between 31 and 60 minutes before incision.[59] As such, current data support administration of the first dose of prophylactic antibiotics within 60 minutes before surgical incision. For antibiotics that require longer infusion times (vancomycin, fluoroquinolones), administration may begin within 120 minutes before incision. Redosing of antibiotics should be performed to maintain therapeutic serum levels, generally after every two half-lives or if there is blood loss greater than 1500 mL (Table 19.18).

Duration of antimicrobial administration should be limited to the minimal effective length appropriate for each procedure. Most clean and clean-contaminated operations do not require postoperative antimicrobial administration; when indicated, postoperative antimicrobials should be limited to less than 24 hours. The evidence for short-duration or single-dose prophylaxis in cardiothoracic surgery has been inconsistent, and optimal antimicrobial duration after these operations remains contentious. Although the Society of Thoracic Surgeons recognizes risks for resistance and superinfection with *Clostridioides difficile* with prolonged antibiotic administration, there is evidence that antibiotic duration up to 48 hours reduces the risk of a sternal wound infection. Thus, the Surgical Infection Society and the Society of Thoracic Surgeons both recommend consideration of antimicrobial prophylaxis for up to 48 hours after cardiothoracic surgery.

Review of Medications

Management of home medications on the day of surgery should be tailored to the patient and the operation. The objective is to minimize disruption of baseline homeostasis while limiting risks of surgical bleeding and drug-drug interactions with anesthetic medications. A preoperative review of medications is mandatory, with attention to cardiac, psychiatric, neurologic, and diabetic medications as well as anticoagulants and antiplatelet agents. In general, cardiac drugs and inhalers should be continued on the morning of surgery. In the postoperative setting, parenteral substitutes should be administered as indicated to minimize therapeutic lapse and avoid withdrawal symptoms such as rebound hypertension. Drugs that affect perioperative bleeding risk should be discontinued preoperatively based on the drug's half-life. Institutional guidelines regarding timing for withholding antiplatelets and anticoagulants before local analgesic procedures such as epidural placement or spinal/regional blockade should be reviewed with the patient during the preoperative clinic visit.

TABLE 19.16 Wound Classification

WOUND CLASSIFICATION	DEFINITION
Clean	An uninfected operative wound in which no inflammation is encountered and the respiratory, alimentary, genital, or uninfected urinary tracts are not entered.
Clean-contaminated	Operative wounds in which the respiratory, alimentary, genital, or urinary tracts are entered under controlled conditions and without unusual contamination. Specifically, operations involving the biliary tract, appendix, vagina, and oropharynx, provided no evidence of infection or major break in technique is encountered.
Contaminated	Open, fresh, accidental wounds. In addition, operations with major breaks in sterile technique or gross spillage from the gastrointestinal tract and incisions in which acute, nonpurulent inflammation is encountered, including necrotic tissue without evidence of purulent drainage.
Dirty-infected	Old traumatic wounds with retained devitalized tissue and those that involve existing clinical infection or perforated viscera. Organisms causing postoperative infection were present in the operative field before the operation.

TABLE 19.17 Recommendations for Surgical Antimicrobial Prophylaxis

TYPE OF PROCEDURE	RECOMMENDED AGENTS[a,b]	ALTERNATIVE AGENTS IN PATIENTS WITH β-LACTAM ALLERGY	STRENGTH OF EVIDENCE[c]
Cardiac coronary artery bypass	Cefazolin, cefuroxime	Clindamycin,[d] vancomycin[d]	A
Cardiac device insertion procedures (e.g., pacemaker implantation)	Cefazolin, cefuroxime	Clindamycin, vancomycin	A
Ventricular assist devices	Cefazolin, cefuroxime	Clindamycin, vancomycin	C
Thoracic noncardiac procedures, including lobectomy, pneumonectomy, lung resection, and thoracotomy	Cefazolin. ampicillin-sulbactam	Clindamycin,[d] vancomycin[d]	A
Video-assisted thoracoscopic surgery	Cefazolin. ampicillin-sulbactam	Clindamycin,[d] vancomycin[d]	C
Gastroduodenal[e] procedures involving entry into lumen of gastrointestinal tract (bariatric, pancreaticoduodenectomy[f])	Cefazolin	Clindamycin or vancomycin + aminoglycoside[g] or aztreonam or fluoroquinolone[h-j]	A
Procedures without entry into gastrointestinal tract (antireflux, highly selective vagotomy) for high-risk patients	Cefazolin	Clindamycin or vancomycin + aminoglycoside[g] or aztreonam or fluoroquinolone[h-j]	A
Biliary tract open procedure	Piperacillin-tazobactam, cefazolin, cefoxitin, cefotetan, ceftriaxone,[k] ampicillin-sulbactam[h]	Clindamycin or vancomycin + aminoglycoside[g] or aztreonam or fluoroquinolone,[h-j] metronidazole + aminoglycoside[g] or fluoroquinolone[h-j]	A
Laparoscopic procedure			
Elective, low-risk[l]	None	None	A
Elective, high-risk[l]	Cefazolin, cefoxitin, cefotetan, ceftriaxone,[k] ampicillin-sulbactam[h]	Clindamycin or vancomycin + aminoglycoside[g] or aztreonam or fluoroquinolone,[h-j] metronidazole + aminoglycosid[g] or fluoroquinolone[h-j]	A
Appendectomy for uncomplicated appendicitis	Cefoxitin, cefotetan, cefazolin + metronidazole	Clindamycin + aminoglycoside[g] or aztreonam or fluoroquinolone,[h-j] metronidazole + aminoglycoside[g] or fluoroquinolone[h-j]	A
Small intestine			
Nonobstructed	Cefazolin	Clindamycin + aminoglycoside[g] or aztreonam or fluoroquinolone[h-j]	C
Obstructed	Cefazolin + metronidazole, cefoxitin, cefotetan	Metronidazole + aminoglycoside[g] or fluoroquinolone[h-j]	C
Hernia repair (hernioplasty and herniorrhaphy)	Cefazolin	Clindamycin, vancomycin	A
Colorectal[m]	Cefazolin + metronidazole, cefoxitin, cefotetan, ampicillin-sulbactam,[h] ceftriaxone + metronidazole,[n] ertapenem	Clindamycin + aminoglycoside[g] or aztreonam or fluoroquinolone,[h-j] metronidazole + aminoglycoside[5] or fluoroquinolon[h-j]	A
Head and neck clean	None	None	B
Clean with placement of prosthesis (excludes tympanostomy tubes)	Cefazolin, cefuroxime	Clindamycin[d]	C
Clean-contaminated cancer surgery	Cefazolin + metronidazole, cefuroxime + metronidazole, ampicillin-sulbactam	Clindamycin[d]	A
Other clean-contaminated procedures with the exception of tonsillectomy and functional endoscopic sinus procedures	Cefazolin + metronidazole, cefuroxime + metronidazole, ampicillin-sulbactam	Clindamycin[d]	0
Neurosurgery elective craniotomy and cerebrospinal fluid-shunting procedures	Cefazolin	Clindamycin,[d] vancomycin[d]	A
Implantation of intrathecal pumps	Cefazolin	Clindamyci,[d] vancomycin[d]	C
Cesarean delivery	Cefazolin	Clindamycin + aminoglycoside[g]	A

TABLE 19.17 Recommendations for Surgical Antimicrobial Prophylaxis—cont'd

TYPE OF PROCEDURE	RECOMMENDED AGENTS[a,b]	ALTERNATIVE AGENTS IN PATIENTS WITH β-LACTAM ALLERGY	STRENGTH OF EVIDENCE[c]
Hysterectomy (vaginal or abdominal)	Cefazolin. cefotetan, cefoxitin, ampicillin-sulbactam[h]	Clindamycin or vancomycin + aminoglycoside[g] or aztreonam or fluoroquinolone,[h-j] metronidazole + aminoglycoside[g] or fluoroquinolone[h-j]	A
Ophthalmic	Topical neomycin-polymyxin B-gramicidin or fourth-generation topical fluoroquinolones (gatifloxacin or moxifloxacin) given as 1 drop every 5–15 minutes for 5 doses.[o] Addition of cefazolin 100 mg by subconjunctival injection or intracameral cefazolin 1–2.5 mg or cefuroxime 1 mg at the end of procedure is optional.	None	0
Orthopedic clean operations involving hand, knee, or foot and not involving implantation of foreign materials	None	None	C
Spinal procedures with and without instrumentation	Cefazolin	Clindamycin,[d] vancomycin[d]	A
Hip fracture repair	Cefazolin	Clindamycin,[d] vancomycin[d]	A
Implantation of internal fixation devices (e.g., nails, screws, plates, wires)	Cefazolin	Clindamycin,[0] vancomycin[3]	C
Total joint replacement	Cefazolin	Clindamycin,[d] vancomycin[d]	**A**
Urologic lower tract instrumentation with risk factors for infection (includes transrectal prostate biopsy)	Fluoroquinolone,[h-j] trimethoprim-sulfamethoxazole, cefazolin	Aminoglycoside[g] with or without clindamycin	**A**
Clean without entry into urinary tract	Cefazolin (addition of a single dose of an aminoglycoside may be recommended for placement of prosthetic material [e.g., penile prosthesis])	Clindamycin,[d] vancomycin[d]	**A**
Involving implanted prosthesis	Cefazolin ± aminoglycoside, cefazolin ± aztreonam, ampicillin-sulbactam	Clindamycin ± aminoglycoside or aztreonam, vancomycin ± aminoglycoside or aztreonam	**A**
Clean with entry into urinary tract	Cefazolin (addition of a single dose of an aminoglycoside may be recommended for placement of prosthetic material [e.g., penile prosthesis])	Fluoroquinolone,[h-j] aminoglycoside[g] ± clindamycin	**A**
Clean-contaminated	Cefazolin + metronidazole, cefoxitin	Fluoroquinolone,[h-j] aminoglycoside[g] + metronidazole or clindamycin	**A**
Vascular[p]	Cefazolin	Clindamycin,[d] vancomycin[d]	**A**
Heart, lung, heart-lung transplantation[q]; heart transplantation[r]	Cefazolin	Clindamycin,[d] vancomycin[d]	A (based on cardiac procedures)
Lung and heart-lung transplantation[r,s]	Cefazolin	Clindamycin,[d] vancomycin[d]	A (based on cardiac procedures)
Liver transplantation[q,t]	Piperacillin-tazobactam, cefotaxime + ampicillin	Clindamycin or vancomycin + aminoglycoside[g] or aztreonam or fluoroquinolone[h-j]	0
Pancreas and pancreas-kidney transplantation[r]	Piperacillin-tazobactam, cefazolin, fluconazole (for patients at high risk of fungal infection [e.g., patients with enteric drainage of the pancreas])	Clindamycin or vancomycin + aminoglycoside[g] or aztreonam or fluoroquinolone[h-j]	**A**
	Cefazolin	Clindamycin or vancomycin + aminoglycoside[g] or aztreonam or fluoroquinolone[h-j]	A

TABLE 19.17 **Recommendations for Surgical Antimicrobial Prophylaxis—cont'd**

TYPE OF PROCEDURE	RECOMMENDED AGENTS[a,b]	ALTERNATIVE AGENTS IN PATIENTS WITH β-LACTAM ALLERGY	STRENGTH OF EVIDENCE[c]
Plastic surgery clean with risk factors or clean-contaminated	Cefazolin, ampicillin-sulbactam	Clindamycin,[d] vancomycin[d]	C

[a] The antimicrobial agent should be started within 60 minutes before surgical incision (120 minutes for vancomycin or fluoroquinolones). Although single-dose prophylaxis is usually sufficient, the duration of prophylaxis for all procedures should be <24 hours. If an agent with a short half-life is used (e.g., cefazolin, cefoxitin), it should be readministered if the procedure duration exceeds the recommended redosing interval (from the time of initiation of the preoperative dose). Readministration may also be warranted if prolonged or excessive bleeding occurs or if there are other factors that may shorten the half-life of the prophylactic agent (e.g., extensive burns). Readministration may not be warranted in patients in whom the half-life of the agent may be prolonged (e.g., patients with renal insufficiency or renal failure).

[b] For patients known to be colonized with methicillin-resistant *Staphylococcus aureus,* it is reasonable to add a single preoperative dose of vancomycin to the recommended agents.

[c] Strength of evidence that supports the use or nonuse of prophylaxis is classified as A (levels I–III), B (levels IV–VI), or C (level VII). Level I evidence is from large, well-conducted, randomized controlled clinical trials. Level II evidence is from small, well-conducted, randomized controlled clinical trials. Level III evidence is from well-conducted cohort studies. Level IV evidence is from well-conducted case-control studies. Level V evidence is from uncontrolled studies that were not well conducted. Level VI evidence is conflicting evidence that tends to favor the recommendation. Level VII evidence is expert opinion.

[d] For procedures in which pathogens other than staphylococci and streptococci are likely, an additional agent with activity against those pathogens could be considered. For example, if there are surveillance data showing that gram-negative organisms are a cause of surgical site infections for the procedure, practitioners may consider combining clindamycin or vancomycin with another agent (cefazolin if the patient is not allergic to β-lactam antibiotics; aztreonam, gentamicin, or single-dose fluoroquinolone if the patient is allergic to β-lactam antibiotics).

[e] Prophylaxis should be considered for patients at highest risk for postoperative gastroduodenal infections, such as patients with increased gastric pH (e.g., patients receiving histamine H2 receptor antagonists or proton pump inhibitors), gastroduodenal perforation, decreased gastric motility, gastric outlet obstruction, gastric bleeding, morbid obesity, or cancer. Antimicrobial prophylaxis may not be needed when the lumen of the intestinal tract is not entered.

[f] Consider additional antimicrobial coverage with infected biliary tract.

[g] Gentamicin or tobramycin.

[h] Because of increasing resistance of *Escherichia coli* to fluoroquinolones and ampicillin-sulbactam, local population susceptibility profiles should be reviewed before use.

[i] Ciprofloxacin or levofloxacin.

[j] Fluoroquinolones are associated with an increased risk of tendinitis and tendon rupture in patients of all ages. However, this risk would be expected to be quite small with single-dose antibiotic prophylaxis. Although the use of fluoroquinolones may be necessary for surgical antibiotic prophylaxis in some children, they are not first-choice drugs in pediatric patients because of an increased incidence of adverse events compared with control subjects in some clinical trials.

[k] Ceftriaxone use should be limited to patients requiring antimicrobial treatment for acute cholecystitis or acute biliary tract infections that may not be determined before incision; ceftriaxone should not be used in patients undergoing cholecystectomy for noninfected biliary conditions, including biliary colic or dyskinesia without infection.

[l] Factors that indicate a high risk of infectious complications in laparoscopic cholecystectomy include emergency procedures, diabetes, long procedure duration, intraoperative gallbladder rupture, age >70 years, conversion from laparoscopic to open cholecystectomy, American Society of Anesthesiologists classification of ≥3, episode of colic within 30 days before the procedure, reintervention in <1 month for noninfectious complication, acute cholecystitis, bile spillage, jaundice, pregnancy, nonfunctioning gallbladder, immunosuppression, and insertion of prosthetic device. Because many of these risk factors are impossible to determine before surgical intervention, it may be reasonable to give a single dose of antimicrobial prophylaxis to all patients undergoing laparoscopic cholecystectomy.

[m] For most patients, a mechanical bowel preparation combined with oral neomycin sulfate plus oral erythromycin base or with oral neomycin sulfate plus oral metronidazole should be given in addition to IV prophylaxis.

[n] In cases in which there is increasing resistance to first-generation and second-generation cephalosporins among gram-negative isolates from surgical site infections, a single dose of ceftriaxone plus metronidazole may be preferred over the routine use of carbapenems.

[o] The necessity of continuing topical antimicrobials postoperatively has not been established.

[p] Prophylaxis is not routinely indicated for brachiocephalic procedures. Although there are no data to support it, patients undergoing brachiocephalic procedures involving vascular prostheses or patch implantation (e.g., carotid endarterectomy) may benefit from prophylaxis.

[q] These guidelines reflect recommendations for perioperative antibiotic prophylaxis to prevent surgical site infections and do not provide recommendations for prevention of opportunistic infections in immunosuppressed transplantation patients (e.g., for antifungal or antiviral medications).

[r] Patients who have left ventricular assist devices as a bridge and who experience chronic infection might also benefit from coverage of the infecting microorganism.

[s] The prophylactic regimen may need to be modified to provide coverage against any potential pathogens, including gram-negative (e.g. *Pseudomonas aeruginosa*) or fungal organisms, isolated from the donor lung or the recipient before transplantation. Patients undergoing lung transplantation with negative cultures before transplantation should receive antimicrobial prophylaxis as appropriate for other types of cardiothoracic surgeries. Patients undergoing lung transplantation for cystic fibrosis should receive 7–14 days of treatment with antimicrobials selected according to culture before transplantation and susceptibility results. This treatment may include additional antibacterial or antifungal agents.

[t] The prophylactic regimen may need to be modified to provide coverage against any potential pathogens, including vancomycin-resistant enterococci, isolated from the recipient before transplantation.

TABLE 19.18 Clinical Practice Guidelines for Antimicrobial Prophylaxis in Surgery

	RECOMMENDED DOSE			
ANTIMICROBIAL	ADULTS[a]	CHILDREN[b]	HALF-LIFE IN ADULTS WITH NORMAL RENAL FUNCTION (H)[58]	RECOMMENDED REDOSING INTERVAL (FROM INITIATION OF PREOPERATIVE DOSE) (H)[c]
Ampicillin-sulbactam	3 g (ampicillin 2 g/sulbactam 1 g)	50 mg/kg of ampicillin component	0.8–1.3	2
Ampicillin	2 g	50 mg/kg	1–1.9	2
Aztreonam	2 g	30 mg/kg	1.3–2.4	4
Cefazolin	2 g, 3 g for patients weighing ≥120 kg	30 mg/kg	1.2–2.2	4
Cefuroxime	1.5 g	50 mg/kg	1–2	4
Cefotaxime	1 g[d]	50 mg/kg	0.9–1.7	3
Cefoxitin	2 g	40 mg/kg	0.7–1.1	2
Cefotetan	2 g	40 mg/kg	2.8–4.6	6
Ceftriaxone	2 g[e]	50–75 mg/kg	5.4–10.9	NA
Ciprofloxaci[f]	400 mg	10 mg/kg	3–7	NA
Clindamycin	900 mg	10 mg/kg	2–4	6
Ertapenem	1 g	15 mg/kg	3–5	NA
Fluconazole	400 mg	6 mg/kg	30	NA
Gentamicin[g]	5 mg/kg based on dosing weight (single dose)	2.5 mg/kg based on dosing weight	2–3	NA
Levofloxacin[f]	500 mg	10 mg/kg	6–8	NA
Metronidazole	500 mg	15 mg/kg; neonates weighing <1200 g should receive a single 7.5-mg/kg dose	6–8	NA
Moxifloxacin[f]	400 mg	10 mg/kg	8–15	NA
Piperacillin-tazobactam	3.375 g	Infants 2–9 months: 80 mg/kg of piperacillin component Children >9 months and ≤40 kg: 100 mg/kg of piperacillin component	0.7–1.2	2
Vancomycin	15 mg/kg	15 mg/kg	4–8	NA
Oral Antibiotics for Colorectal Surgery Prophylaxis (Used in Conjunction With Mechanical Bowel Preparation)				
Erythromycin base	1 g	20 mg/kg	0.8–3	NA
Metronidazole	1 g	15 mg/kg	6–10	NA
Neomycin	1 g	15 mg/kg	2–3 (3% absorbed under normal gastrointestinal conditions)	NA

[a] Adult doses are obtained from different studies.

[b] The maximum pediatric dose should not exceed the usual adult dose.

[c] For antimicrobials with a short half-life (e.g., cefazolin, cefoxitin) used before long procedures, redosing in the operating room is recommended at an interval of approximately two times the half-life of the agent in patients with normal renal function. Recommended redosing intervals marked as NA are based on typical case length; for unusually long procedures, redosing may be needed.

[d] Although Food and Drug Administration–approved package insert labeling indicates 1 g, experts recommend 2 g for obese patients.

[e] When used as a single dose in combination with metronidazole for colorectal procedures.

[f] Although fluoroquinolones have been associated with an increased risk of tendinitis or tendon rupture in patients of all ages, use of these agents for single-dose prophylaxis is generally safe.

[g] In general, gentamicin for surgical antibiotic prophylaxis should be limited to a single dose given preoperatively. Dosing is based on the patient's actual body weight. If the patient's actual weight is more than 20% above ideal body weight (IBW), the dosing weight (DW) can be determined as follows: DW = IBW + 0.4 (actual weight − IBW).

NA, Not applicable.

Originally from Bratzler DW, Patchen Dellinger E, Olsen KM, et al. Clinical practice guidelines for antimicrobial prophylaxis in surgery. *Surg Infections (Larchmt).* 2013;14(1):73-156.

Herbal supplements, vitamins, oral contraceptives, and hormonal therapies are often underreported. Estrogen and tamoxifen should be held for 4 weeks preoperatively because of thromboembolic risk. Many herbal medicines can affect perioperative physiology and should be stopped days to weeks before surgery (Table 19.19).

Preoperative Fasting

Bronchopulmonary aspiration can be a life-threatening complication in the perioperative setting. Limiting preoperative oral intake is intended to reduce gastric volume during induction to minimize aspiration risk. There is growing evidence, however, that the traditional protocol of fasting before surgery is not required for aspiration risk reduction. The ASA provided updated practice guidelines for preoperative fasting in 2023. Broadly, clear liquids—with carbohydrate supplementation—are permissible up to 2 hours before elective procedures requiring general anesthesia or procedural sedation. Breast milk may be ingested up to 4 hours before elective procedures. To date, evidence for a specific duration of solid food fasting is lacking. Current guidelines indicate that a light meal may be permissible for up to 6 hours before elective procedures; however, this interval may be lengthened for heavier meals and patients at higher risk for aspiration (Table 19.20). The ASA does not recommend routine administration of gastrointestinal stimulants, antacids, antiemetics, or anticholinergics to reduce aspiration risk or shorten the recommended preoperative fasting period.

OPERATING ROOM

Adequate preparation of the operating room—to ensure the availability and functionality of systems-based resources (e.g., videoendoscopic accessibility, anesthesia team, blood products) and surgical equipment (e.g., instrument sets, stapler and/or energy devices)—is as critical to a successful operation as appropriate patient selection and preoperative evaluation. Systems-based resources include operating room particulars such as temperature control, presurgical cleaning, and availability of anesthesia, pathology, and consultative services. Appropriate preoperative communication with the anesthesia team is imperative, especially when specific perioperative challenges are anticipated. Examples include patients with high-risk cardiac disease, those with significant underlying liver and/or kidney disease, or patients scheduled for high-risk operations where appropriate intraoperative hemodynamic and volume management is imperative. Recent implementation of patient recovery pathways has standardized many aspects

TABLE 19.19 Perioperative Concerns and Recommendations for Herbal Medicines

COMMON NAME OF HERB	PERIOPERATIVE CONCERNS	RELEVANT PHARMACOLOGIC EFFECT	PREOPERATIVE RECOMMENDATIONS
Echinacea	Allergic reactions, decreased effectiveness of immunosuppressants; potential for immunosuppression with long-term use	Activation of cell-mediated immunity	
Ephedra	Risk for myocardial ischemia and stroke from tachycardia and hypertension; ventricular arrhythmias with halothane: long-term use depletes endogenous catecholamines and may cause intraoperative hemodynamic instability; life-threatening interaction with monoamine oxidase inhibitors	Increased heart rate and blood pressure through direct and indirect sympathomimetic effects	Discontinue at least 24 h before surgery
Garlic	Potential to increase risk for bleeding, especially when combined with other medications that inhibit platelet aggregation	Inhibition of platelet aggregation (may be irreversible); increased fibrinolysis; equivocal hypertensive activity	Discontinue at least 7 days before surgery
Ginkgo	Potential to increase risk for bleeding, especially when combined with other medications that inhibit platelet aggregation	Inhibition of platelet-activating factor	Discontinue at least 36 h before surgery
Ginseng	Hypoglycemia; potential to increase risk for bleeding; potential to decrease anticoagulative effect of warfarin	Lowers blood glucose; inhibition of platelet aggregation (may be irreversible); increased PT/PTT in animals	Discontinue at least 7 days before surgery
Kava	Potential to increase sedative effect of anesthetics; potential for addiction, tolerance, and withdrawal after abstinence unstudied	Sedation, anxiolysis	Discontinue at least 24 h before surgery
St. John's wort	Induction of cytochrome P450 enzymes, with effect on cyclosporine, warfarin, steroids, and protease inhibitors and possibly benzodiazepines, calcium channel blockers, and many other drugs; decreased serum digoxin levels	Inhibition of neurotransmitter uptake, monoamine oxidase inhibition is unlikely	Discontinue at least 5 days before surgery
Valerian	Potential to increase sedative effect of anesthetics; benzodiazepine-like acute withdrawal; potential to increase anesthetic requirements with long-term use	Sedation	No data

PT, Prothrombin time; *PTT,* partial thromboplastin time.

TABLE 19.20 Recommended Minimum Fasting Periods Between Oral Intake and General Anesthesia for Elective Operations

INGESTED MATERIAL	MINIMUM FASTING PERIOD
Clear liquids	2 hours
Breast milk	4 hours
Infant formula	6 hours
Nonhuman milk	6 hours
Light meal	6 hours
Fried foods and meat	8+ hours

Adapted from Practice Guidelines for Preoperative Fasting and the Use of Pharmacologic Agents to Reduce the Risk of Pulmonary Aspiration: Application to Healthy Patients Undergoing Elective Procedures: An Updated Report by the American Society of Anesthesiologists Task Force on Preoperative Fasting and the Use of Pharmacologic Agents to Reduce the Risk of Pulmonary Aspiration. *Anesthesiology.* 2017; 126(3):376-393.

of anesthetic care; however, active communication between the surgery and anesthesiology teams remains important to ensure the most appropriate intraoperative management. Additional system-based resources include medications and products necessary in the immediate perioperative period such as analgesics, fluids, blood products, antibiotics, anticoagulants, and vasoactive drugs. Also important is the presence of appropriate surgical assistance and backup. Despite diligent preoperative planning, complex operations frequently encounter unforeseen and potentially life-threatening intraoperative challenges. Immediate availability of experienced surgeon partners and consultative services should be verified before every operation.

Although the specific assembly of surgical instruments will always depend on the operation at hand, common equipment should be available for any operation. Expected equipment includes appropriate lighting, a properly functioning operating table, surgical instruments, monitors to display preoperative imaging, a suction mechanism, and coagulation instrumentation. For minimally invasive operations, insufflation equipment, trocars, a camera, video monitors, laparoscopic and/or robotic instruments, and resources should be clearly communicated and verified. Progress in robotic-assisted laparoscopy has delivered significant benefits in the realm of minimally invasive surgery, offering superior visualization, enhanced mechanical capabilities, improved surgeon ergonomics, and complete instrument articulation in comparison to conventional laparoscopy. Robotic surgery, despite its numerous advantages, is not without some limitations. One notable constraint is the high cost of acquiring and maintaining robotic systems. Additionally, the setup and preparation for robotic procedures can be time consuming, leading to longer anesthesia times. Surgeons also require specialized training to operate the systems effectively. Furthermore, there is a lack of tactile feedback in robotic surgery, which may affect the surgeon's ability to sense tissue characteristics.[60]

The patient should be positioned securely while minimizing pressure points to prevent neuromuscular injury. For obese patients and patients in lithotomy position, the risk for extremity compartment syndrome, peripheral nerve injuries, and deep soft tissue injury (i.e., pressure ulcers) should be acknowledged and minimized, particularly for long operations. Fluid-impermeable drapes and gowns should be used to create a sterile barrier between the operative field and the ambient environment.

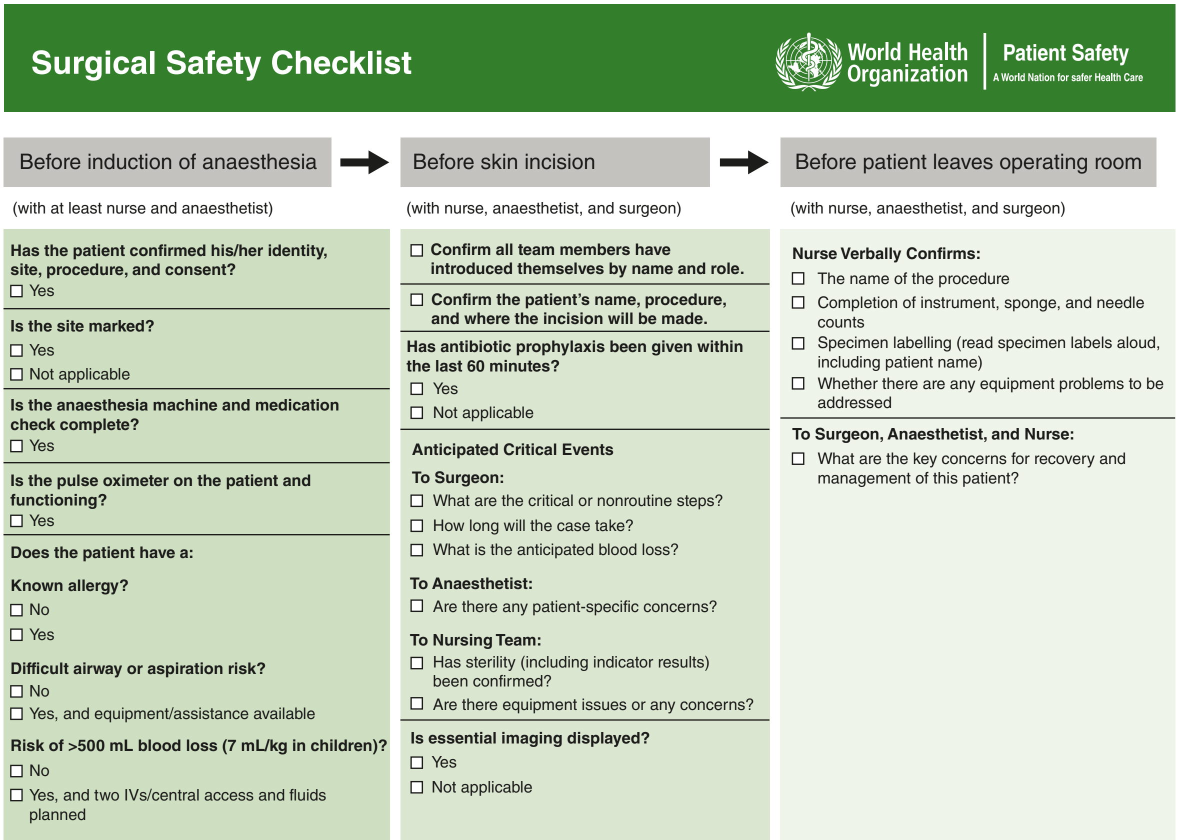
The importance of communication between the surgery team, anesthesiology team, and operating room nursing staff cannot be overemphasized. Clear dialogue is necessary to improve focus, eliminate or reduce confusion, and enable anticipation. A preoperative time-out process has been implemented in most institutions (Fig. 19.8); it standardizes immediate preoperative preparation of the "surgical team." Continually updating all parties in the operating room regarding key steps of the operation is vital to minimize risk to the patient and reduce delays because of equipment unavailability. Finally, best practice uses closed-loop communication techniques to ensure communication is heard, understood, and acknowledged by all parties.

Maintenance of Normothermia

Thermoregulation is based on systemic input integrated by the central nervous system, primarily the hypothalamus and spinal cord. Under normal conditions, autonomic control regulates core temperature consistently to between 36°C and 38°C. General anesthesia lowers the cold-response threshold of the body. Volatile and intravenous anesthetics impair thermoregulation, paralytics prevent the body's shivering response to hypothermia, and compensatory vasoconstriction is downregulated. Regional neuroaxial anesthesia (e.g., epidural and spinal) further blunts thermoregulatory control by reducing thermal discomfort and blocking efferent nervous control of vasoconstriction and shivering. The effects of general and regional anesthesia are roughly additive[61]; this factor is particularly relevant because of an increase in usage of regional anesthesia as a component of modern ERAS pathways. An additional factor is large-volume cavity exposure (abdominal or thoracic) that significantly contributes to heat loss. Risk of hypothermia is increased in the elderly, females, and the malnourished during long operations.

Consequences of intraoperative hypothermia are myriad. Platelet aggregation and the coagulation cascade are impaired, resulting in an association between hypothermia and nearly a 20% increased operative blood loss. Because of vasoconstriction and the consequent decreased oxygenation of surgical incisions, hypothermia has been associated with an increased rate of wound infection. Finally, hypothermia alters drug actions/metabolism such that the duration of action of many anesthetics is prolonged and correction of acidosis and electrolyte disarray is impaired. Close monitoring of core body temperature throughout the operation is mandatory. The best and most pragmatic monitoring site is the distal esophagus for intubated patients. Sublingual, axillary, and bladder temperatures also correlate well with core body temperature. Conversely, skin, forehead, external aural canal, and rectal temperatures correlate poorly with core temperature.[61]

Hypothermia is most drastic within the first hour after induction because of the rapid effect of anesthesia-induced vasodilation. Therefore, it is during this period that rewarming techniques are most critical. Rewarming can take the form of passive or active methods. Passive insulation (e.g., blankets, sheets) can reduce cutaneous heat loss by roughly 30%. Increasing ambient room temperature can passively mitigate heat loss but is impractical for raising core body temperature. Active warming with forced air is frequently effective during induction and throughout the operation to compensate for rapid thermal dysregulation. Forced air is the most common approach because of its ease of use, effectiveness, and low cost. Contrary to popular belief, intravenous fluid warming is relatively ineffective because infused fluid temperatures cannot significantly exceed the body's core temperature. However, patients can be *cooled* by infusion of ambient-temperature



Surgical Safety Checklist

World Health Organization
Patient Safety
A World Alliance for safer Health Care

Before induction of anaesthesia

(with at least nurse and anaesthetist)

Has the patient confirmed his/her identity, site, procedure, and consent?
☐ Yes

Is the site marked?
☐ Yes
☐ Not applicable

Is the anaesthesia machine and medication check complete?
☐ Yes

Is the pulse oximeter on the patient and functioning?
☐ Yes

Does the patient have a:

Known allergy?
☐ No
☐ Yes

Difficult airway or aspiration risk?
☐ No
☐ Yes, and equipment/assistance available

Risk of >500 mL blood loss (7 mL/kg in children)?
☐ No
☐ Yes, and two IVs/central access and fluids planned

Before skin incision

(with nurse, anaesthetist, and surgeon)

☐ **Confirm all team members have introduced themselves by name and role.**

☐ **Confirm the patient's name, procedure, and where the incision will be made.**

Has antibiotic prophylaxis been given within the last 60 minutes?
☐ Yes
☐ Not applicable

Anticipated Critical Events

To Surgeon:
☐ What are the critical or nonroutine steps?
☐ How long will the case take?
☐ What is the anticipated blood loss?

To Anaesthetist:
☐ Are there any patient-specific concerns?

To Nursing Team:
☐ Has sterility (including indicator results) been confirmed?
☐ Are there equipment issues or any concerns?

Is essential imaging displayed?
☐ Yes
☐ Not applicable

Before patient leaves operating room

(with nurse, anaesthetist, and surgeon)

Nurse Verbally Confirms:
☐ The name of the procedure
☐ Completion of instrument, sponge, and needle counts
☐ Specimen labelling (read specimen labels aloud, including patient name)
☐ Whether there are any equipment problems to be addressed

To Surgeon, Anaesthetist, and Nurse:
☐ What are the key concerns for recovery and management of this patient?

FIGURE 19.8 Surgical safety checklist published by the World Health Organization. (From https://www.who.int/patientsafety/safesurgery/checklist/en/.)

fluids, thereby exacerbating anesthesia-induced hypothermia. Therefore, any intraoperative infusion of >1 L/h should be prewarmed.

Preoperative Skin Preparation

SSIs comprise more than 20% of all hospital-acquired infections and are associated with increased length of stay, mortality, and cost.[62] Commensal skin bacteria (e.g., staphylococci, *Pseudomonas*) are responsible for the majority of superficial SSIs. Preoperative antiseptic skin preparation reduces the number of transient and commensal microorganisms. The CDC guidelines recommend the following techniques for application: (1) a wide area to include any potential incision sites, (2) concentric circle motion, (3) use of a dedicated application instrument, and (4) adequate time to allow the solution to dry. Hair removal before incision can improve exposure and allow skin marking. However, hair should only be removed with a clipper because shaving is associated with increased SSI risk.

The benefits of skin preparation depend on the antiseptic solution used. Common solutions include povidone-iodine scrub and paint (Betadine), chlorhexidine-alcohol scrub (ChloraPrep), and iodine povacrylex with isopropyl alcohol (DuraPrep). Alcohol-containing solutions should be avoided for mucosal surfaces. The optimal choice of antiseptic for intact skin remains controversial. Most randomized trials in the past comparing antiseptic solutions are underpowered. A Cochrane review in 2015 indicated that alcohol-containing products have the greatest probability of being effective but noted the overall low quality of evidence.[63] A multi-institutional randomized comparison of chlorhexidine-alcohol versus povidone-iodine scrub and paint for clean-contaminated surgeries found a lower rate of SSI in the chlorhexidine-alcohol group (9.5% vs. 16.1%).[64] Recently, a single-institution randomized trial of colorectal operations failed to conclude noninferiority of DuraPrep compared with ChloraPrep, with SSI rates of 18.7% versus 15.9%, respectively. Therefore, based on these data, a skin preparation that contains an alcohol-based agent as part of the preparation appears optimal.

Hemostasis

Meticulous dissection and intimate knowledge of surgical anatomy are mandatory for minimization of intraoperative blood loss. Surgical bleeding obscures the operative field, prolongs operating time, increases hemodynamic stress, induces coagulopathy, and makes postoperative resuscitation more challenging. For certain cancers, perioperative blood transfusion has consistently been associated with an increased risk of recurrence and a decrease in survival.

Although capillaries and small veins can be controlled and divided with monopolar electrocautery alone, vessels >1 mm in diameter—including all named vessels—are best controlled with ties, clips, staples, bipolar electrocautery, or ultrasonic devices. To prevent dislodgement of ties or clips, larger vessels may be controlled by suture ligation. Traditionally, vascular structures are ligated with permanent suture material, though use of absorbable sutures has not been associated with increased risk of bleeding or reoperation. With the rapid expansion of minimally invasive operations and the associated explosion in manufactured surgical devices, numerous alternatives to the traditional hand-tied ligation

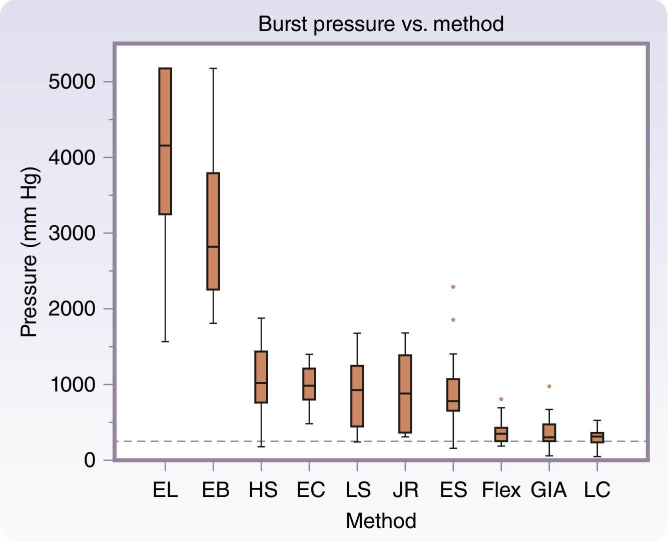


FIGURE 19.9 Burst pressure of porcine carotid artery by sealing method. *EB,* Ethibond hand-tie; *EC,* endoclip; *EL,* endoloop; *ES,* enseal; *Flex,* endopath stapler; *GIA,* endo GIA stapler; *HS,* Harmonic Scalpel; *JR,* JustRight; *LC,* proximate linear cutter; *LS,* LigaSure. (Adapted from Tharakan SJ, Hiller D, Shapiro RM, et al. Vessel sealing comparison: old school is still hip. *Surg Endosc.* 2016;30:4653-4658.)

have been marketed and popularized. In addition to minimally invasive (robotic or laparoscopic) surgical ties, endoloops are most similar to the hand-tie with similar vessel burst pressures comparable to hand-ties.[65] On the other end of the spectrum, stapling devices armed with vascular staple loads tolerate lower—but still supraphysiologic—burst pressures (Fig. 19.9).

Wound Closure

In general, incisions for clean and clean-contaminated operations can be closed primarily. Primary fascial closure can use permanent or dissolvable sutures using running or interrupted techniques. Permanent sutures are best suited for malnourished, debilitated patients and for scenarios in which early outpatient follow-up is anticipated. Dissolvable sutures, particularly when used in the subcuticular layer, can often create a cosmetically appealing closure that does not require suture removal. When an incision is anticipated to be under significant tension, vertical mattress sutures distribute tension over two levels of depth at every longitudinal point and approximate the dermal layers effectively. Running suture techniques—especially when used across multiple layers—are more effective at controlling ascites, and interrupted sutures allow intermittent wound packing for incisions at high risk for superficial SSI.

Delayed primary closure may be suitable for carefully selected patients after contaminated operations. Delayed closure is commonly attempted between 2 and 5 days after the index operation. Although there is some evidence that delayed primary closure is associated with a reduction in SSI compared with primary closure, there is substantial heterogeneity across existing trials.[66] Heavily contaminated dirty surgical wounds should be left open, allowing for healing by secondary intent with serial packing. Management of open wounds during the outpatient recovery period can often be facilitated by applying a negative pressure vacuum device.

Although covered in depth elsewhere (Chapter 37), temporary closure of abdominal incisions is useful when a short-interval second-look laparotomy is anticipated, when there is threat of compartment syndrome, and when monitoring of intraabdominal contents is prudent. In almost all cases, temporary closure involves a nonadherent material used as a bridge across an open fascial incision. Delayed primary fascial closure should be achieved when possible within 7 to 10 days.[67] Bioprosthetic dermal matrices have gained favor as an alternative material for fascial bridging; however, there is a paucity of large published series capturing experience with Acellular dermal matrix (ADM), and recurrent hernia and abdominal laxity may develop with longer follow-up.[68]

Use of barrier agents for adhesion prevention has gained popularity over recent years, particularly for patients for whom multiple operations are anticipated. Agents include oxidized regenerated cellulose, polytetrafluoroethylene, and hyaluronic acid–carboxymethylcellulose. These materials are applied to the raw surfaces of abdominal viscera and degenerate into gelatin shortly after surgery. A meta-analysis within the gynecologic literature noted low-quality evidence of efficacy for all three materials over no treatment; however, the relative efficacy between agents remains unclear.[69]

Surgical Adhesives

Tissue adhesives for skin closure were first introduced in the early 1960s. Over the past 30 years, improved tensile strength was brought about by plastic and stabilizer composites. The most common adhesives are Dermabond (octylcyanoacrylate), Indermil (Covidien), and Histoacryl (butylcyanoacrylate). Inherent benefits of tissue adhesives include water impermeability, low infection rate, and improved cosmesis. Adhesives can be used without skin sutures for small incisions and are commonly adopted in this manner in the emergency room or outpatient setting. For larger incisions, tissue adhesives are more commonly used to provide a watertight barrier after subcuticular or dermal closure with absorbable suture. A recent meta-analysis found no significant difference between tissue adhesives and sutures in terms of dehiscence, infection, and surgeon-rated cosmesis.[70]

Fibrin sealant confers both adhesive and hemostatic functions. Blood bank–derived fibrin sealant functions by combining thrombin and fibrinogen to replicate the final step in the clotting cascade. Because the agent contains all necessary components for this reaction, it forms a clot regardless of a patient's intrinsic pathway status. Randomized trials have found the addition of fibrin sealant to be superior to manual compression alone in controlling anastomotic hemorrhage after placement of polytetrafluoroethylene vascular grafts.[71] Although fibrin sealant has also been approved as an adjunct for gastrointestinal anastomoses, application for this purpose has not gained widespread popularity, and there are conflicting results in the literature as to a clinical benefit.[72] Fibrin agents have been adopted for a variety of other clinical applications. For perianal fistulae, fibrin glue avoids an adverse impact on continence; however, it exhibits inferior durability compared with conventional surgical treatment. Fibrin glue has been used to treat bronchopleural fistulae, either as a direct injection of fibrinogen followed by topical thrombin or as a diluted pleurodesis agent.

SURGICAL DEVICES, ENERGY SOURCES, AND STAPLERS

Technologic advances in energy devices and tissue stapling have revolutionized the way surgeons approach dissection, division, hemostasis, and reconstruction. As a whole, energy devices direct focused energy to the target tissue with the purpose of dissection and division, coagulation, or ablation and cytotoxicity. Stapling devices are traditionally used for alimentary tract division and anastomosis but can also be used for vascular and tissue transection. This section focuses on some of the common energy and stapling devices encountered in the operating room.

Electrosurgery and Electrocautery

Although use of electricity to induce thermal cauterization and tissue division has been reported since the mid-1800s, modern electrosurgery as we know it was introduced between 1914 and 1927 by William T Bovie. Diathermy—first described by Karl Franz in 1909—uses high-frequency electric currents to generate heat and penetrate tissues. Bovie developed a commercially available alternating current cautery device between 1914 and 1927, and Harvey Cushing popularized it with a 1928 report of 500 neurosurgical procedures.

Monopolar Electrosurgery

In strict terms, electrocautery implies thermal conduction via a probe heated by a direct electrical current. In modern surgery, this technology most commonly is seen with portable, pen-type cautery devices that function like a soldering iron. Electrosurgery, on the other hand, indicates conduction of an alternating radiofrequency current through a circuit that is completed by the patient's tissue. However, these two terms are often used interchangeably. Classically, monopolar electrosurgery is performed using a current generator, a handheld electrode that delivers current to the patient, and a second large electrode (the "pad") that returns current to complete the circuit. The application electrode has a small area of contact, resulting in focused thermal conversion, while the returning electrode has a large surface area to dissipate energy. With a continuous waveform ("cut" mode), the monopolar device cuts through tissue with little thermal spread and minimal coagulation. With an intermittent waveform ("coagulation" mode), current is delivered over less than 10% of the time that the device is activated and is interspersed with short periods of inactivity. The result is lower thermal energy and greater thermal spread, resulting in tissue dehydration and vessel thrombosis. Many surgeons adopt a blended waveform setting ("blend" mode), which replaces the pure cutting function with small periods of current inactivity to achieve a partial coagulative effect.

Bipolar Electrosurgery

Bipolar devices place the delivering and returning electrodes in close proximity in a single device. In this way, the tissue in between the two electrodes completes the electric circuit. A grounding pad is unnecessary, and thermal spread beyond the tissue between the two electrodes is minimal. By compressing vascularized tissue using bipolar forceps, blood is excluded from the circuit, improving heat delivery to the compressed tissue. Bipolar devices are most useful when precise coagulation is necessary in close proximity to vital structures. Because current is only delivered across tissue between the two handheld electrodes, bipolar devices are safe to use when a patient has an implanted electronic device that may otherwise be affected by the delivery of monopolar current.

Bipolar Fusion Devices

An adaptation of bipolar electrosurgery is the bipolar fusion device such as LigaSure and Enseal. Similar to conventional bipolar electrosurgery, these tissue dissection and division devices transmit current between two adjacent electrodes, causing tissue coagulation. By applying uniform compression of the target tissue and monitoring tissue impedance between the jaws of the instrument, these devices adjust energy delivery during the activation process to minimize thermal spread and seal larger vessels (up to 7 mm). Denaturation followed by cross-linking of collagen and elastin results in a natural tissue sealant. A blade within the instrument then divides the sealed tissue.

Saline-Cooled Radiofrequency Dissectors

A commonly encountered problem when using radiofrequency electrosurgery within highly vascularized parenchyma is the formation of dense eschar that limits coagulation and may result in delayed hemorrhage. Eschar formation occurs when temperature at the contact surface of the target tissue exceeds what is necessary for protein denaturation and vessel sealing. Saline-cooled radiofrequency dissectors (i.e., TissueLink, Aquamantys) overcome this issue by directing a steady irrigation stream of saline to the tissue contact point, thereby maintaining surface temperature <105°C. These devices are used mostly during dissection of solid organ parenchyma such as the liver or kidney. Initial division of the organ capsule is necessary (often by traditional Bovie electrosurgery) to prevent steam buildup beneath the capsule. Constant pressure with the saline-linked device is then used to achieve a constant depth of coagulation before sharp transection of the denatured tissue or clipping of larger vessels within the treatment zone.

Ultrasonic Dissectors

A distinction should be made between the use of high-frequency oscillation instruments and true ultrasonic energy technology. The classic example of therapeutic ultrasound is extracorporeal shock wave lithotripsy, through which high-energy acoustic shock waves are directed at pathologic stones to shatter material and facilitate passage. Although lithotripsy has historically been applied to symptomatic cholelithiasis, current applications are primarily focused on urologic stones and pancreatic duct stones. Shock wave lithotripsy is effective primarily for smaller stones (<2 cm) with lower radiographic density.

Harmonic Scalpel

The Harmonic Scalpel transduces high-frequency ultrasonic energy through a metallic jaw to generate mechanical vibration. When in contact with tissue, the vibration of a single blade against a static blade results in vaporization and coagulation. The coagulation effect is increased by compressing the target tissue between the two jaws of the instrument. The energy transduced through the metallic jaw is modifiable; high energy settings result in rapid cutting, whereas low energy promotes coagulation. Because the mechanism for the scalpel is vibration, the instrument divides tissue without the need for a separate cutting blade.

Cavitron Ultrasound Surgical Aspirator

The cavitron ultrasound surgical aspirator (CUSA) uses ultrasonic frequency vibration to selectively dissect parenchymal tissue. The device directs ultrasonic frequency along a hollow titanium tip that vibrates longitudinally to fragment target tissue. Hepatocytes are particularly susceptible to oscillatory fragmentation because of their high-water content, whereas endothelium and epithelium (blood vessels, bile ducts) are selectively spared because of low water content. The CUSA provides a precise dissection plane through this fragmentation process but does not itself confer any vessel-sealing capability. The CUSA tip can be connected to a monopolar electrocautery circuit for tissue ablation and is generally used in conjunction with adjunct methods of hemostasis.

Ablation Technology

Radiofrequency Ablation

Radiofrequency energy delivered via a narrow probe is termed *radiofrequency ablation (RFA).* Applications include esophageal dysplasia, atrial fibrillation, and tumors found within solid organ parenchyma. The RFA probe can be directed toward target tissue via a percutaneous approach or during open or laparoscopic surgery. The electrode at the probe tip transmits high-frequency alternating current to the surrounding tissue, which is converted to kinetic and thermal energy and results in denaturation and coagulation. Because RFA has a similar mechanism as electrosurgery, a grounding pad is necessary, and the presence of implantable electronic devices or metallic surgical clips may be a contraindication. Tissue eschar formation surrounding the electrode has an insulator effect and limits the effective radius of RFA. When performed near a blood vessel, thermal energy is dispersed rapidly from the target tissue, creating a "heat sink" and limiting efficacy. Typically, tumors up to 3 cm can be effectively ablated by RFA; an additional margin of 0.5 cm of healthy parenchyma beyond the target lesion should be ablated to ensure complete ablation of the tumor.

Microwave Ablation

Microwave energy lies between infrared and radio waves in terms of frequency. The impact between microwave energy radiation and polar molecules such as water result in oscillation and frictional heat. Applied to target tissue, the outcome is cell death through coagulative necrosis. Like RFA, microwave ablation (MWA) can be performed percutaneously or during open or minimally invasive surgery and is generally image guided via ultrasound or CT. Advantages over RFA include a larger, more homogeneous zone of ablation, an attenuated heat-sink effect, and less time needed to complete ablation. Because the mechanism of microwave ablation does not involve transmission of electric current, a grounding pad is unnecessary, and use in the presence of metallic clips and implants is safe. Given advantages over RFA without proven disadvantages, MWA is rising in popularity as the preferred technology for tumor ablation in solid organs, including the liver and kidney.

Other Energy Devices

Argon Beam Coagulator

Argon beam coagulation (ABC) was introduced in 1989. Despite its name, ABC is not a laser device, but rather an adaptation of monopolar electrosurgery. A focused beam of argon gas—a strong conductor of electricity—is directed at target tissue. Radiofrequency current is transported from a monopolar electrode to the tissue across this pathway of argon gas. Advantages of ABC over conventional electrosurgery include more rapid activity, shallower penetration, and faster heat dispersion.[73] Moreover, the focused jet of argon gas physically disperses blood from the target tissue, providing a dry environment to promote coagulation and reduce eschar formation. For these reasons, ABC is most suitable for achieving hemostasis over surfaces of solid organ parenchyma, such as the spleen, liver, kidney, lung, and peritoneum. Because of its low depth of penetration, ABC is ineffective for control of larger blood vessels. Moreover, the focused jet of argon gas is insoluble in blood, and direct targeting of central veins can result in cardiac arrest caused by air (argon) embolism. To minimize this risk, surgeons should keep the flow rate of argon gas low, use an angled approach toward the tissue, and avoid direct argon gas deployment into large veins in direct communication with right atrium.

Surgical Staplers

The surgical stapling device was invented in 1907–08 in Budapest, Austria-Hungary. After initial modifications to decrease weight and complexity in the 1920s, surgical staplers were further modified and popularized for use in alimentary tract surgery in the Soviet Union between the 1940s and 1950s. In 1958, a Soviet model of the surgical stapler was brought to the United States. These initial staplers were hand-made with noninterchangeable parts and required loading of individual staples by hand. Development and commercialization of surgical staplers occurred in the United States in the 1960s and 1970s. Designs were optimized for mass production, including interchangeable and disposable stapler cartridges of various staple heights.

At present, a multitude of different surgical staplers can facilitate tissue closure, division, and reconstruction during open, laparoscopic, and robotic operations. Linear cutting staplers (gastrointestinal anastomosis [GIA]) vary in length and staple height to accommodate closure, transection, and reconstruction of variable-thickness tissues. Similarly, linear noncutting staplers (thoracoabdominal [TA]) allow tissue closure without division. Circular cutting staplers (end-to-end anastomosis [EEA]) allow luminal anastomosis and transection of hollow viscera of variable diameters. In terms of staple height, smaller staples (open: 2 mm; closed: 1 mm) are best suited for vascular closure and/or transection, whereas large staples (open: 4.5 mm; closed: 2 mm) are well suited for closure and/or transection of thicker tissues such as the stomach or pancreas. Several in-between staple heights are commercially available for use in intermediate tissue types.

POTENTIAL CAUSES OF INTRAOPERATIVE INSTABILITY

With appropriate patient selection and perioperative preparation, untoward events in the operating room should be rare. Management of rare events, however, requires preparation and anticipation. This section addresses common and potentially deadly causes of intraoperative instability including etiology and management strategies.

Malignant Hyperthermia

Malignant hyperthermia (MH) is an acute episode of hypermetabolism in response to volatile halogenated anesthetic gases (e.g., sevoflurane, isoflurane, and others) and the depolarizing paralytic succinylcholine. Symptoms of MH can occur at any time during general anesthesia or up to 60 minutes after cessation of anesthesia. Intraoperative and/or postoperative manifestations can include fever/hyperthermia, tachycardia, tachypnea, increase in exhaled carbon dioxide, rhabdomyolysis, and metabolic disarray, including hyperkalemia and acidosis. An increase in end-tidal carbon dioxide despite an increase in minute ventilation is one of the earliest intraoperative harbingers of MH. The prevalence of MH has been reported to range from 1 in 10,000 to 1 in 250,000 anesthetic cases. However, prevalence among susceptible individuals with "at-risk" genetic abnormalities is considerably higher. Several genetic mutations that predispose patients to MH have been described (most commonly, a mutation in the *RYR1* gene); the majority of these mutations are autosomal dominant with incomplete penetrance.

When suspected, MH is treated by immediate discontinuation of volatile gases, intravenous administration of dantrolene in doses of 2.5 mg/kg, and body cooling using any available routes. Dantrolene can be redosed every 10 to 15 minutes for ongoing fever, acidosis, and muscle rigidity. Other supportive measures include therapy for arrhythmias, hyperkalemia, and acidosis. Typically, management and observation in the ICU are warranted. With current advances, mortality with MH has decreased from 60% to 80% a few decades ago to less than 5%.

Gas Embolus: Air and Carbon Dioxide

Air embolus is a potentially fatal complication of vascular operations. Similarly, CO_2 embolus can be a fatal complication of minimally invasive laparoscopic or robotic operations. Both are a result of air or CO_2 entering the systemic, most often venous, circulation. In cases of air embolus, air access to the venous system can occur via a planned venotomy during vascular access cases or during repair of great vessels. In contrast, CO_2 embolus occurs more commonly as an unplanned insufflation of gas into the systemic venous circulation. In both cases, an abrupt decrease in end-tidal CO_2 and cardiovascular collapse are the first manifestations, and rapid recognition of symptoms and institution of resuscitative measures are indicated.

In cases of intraoperative cardiovascular collapse because of air or CO_2 embolus, maneuvers allowing access between gas and the vascular system must be terminated. Additionally, cardiopulmonary resuscitation, including pharmacologic agents and mechanical cardiopulmonary resuscitation, have the best chance to achieve return of spontaneous circulation. Intraoperative transesophageal echocardiography can help confirm the diagnosis and measure the amount of gas trapped within the right heart. If there is appropriate vascular access in the right heart, air aspiration can be attempted. Although the Trendelenburg position may be helpful, placing the patient in left lateral decubitus position should only be used in the absence of cardiovascular collapse, as meaningful chest compressions cannot be performed in patients who are not supine. Patients with a patent foramen ovale are at risk for collapse of left ventricular function as well as gas-mediated cerebral embolus. Mortality in patients with gas embolus is approximately 20%.

Myocardial Infarction, Pulmonary Embolus, and Pneumothorax

With appropriate preoperative evaluation, both intraoperative MI and intraoperative PE are rare complications among patients selected for elective general surgery operations. Incidences of both are higher in urgent/emergent operations and operations for traumatic injury. Intraoperative monitoring can demonstrate signs of hemodynamic instability (e.g., tachycardia, hypotension). ECG changes and dysrhythmias are frequently harbingers of cardiac ischemia and/or infarction. Classic ECG changes (e.g., new profound ST elevation) are diagnostic; serum troponin levels can be used to corroborate the diagnosis in hemodynamically stable patients. In the event of a suspected MI and hemodynamic instability, nonemergent operations should be aborted.

PE is rarely suspected when hemodynamic instability is absent. In most cases, for the diagnosis to be considered, intraoperative symptoms include significant tachycardia, hypotension, hypoxia despite high oxygen fraction, and/or cardiovascular collapse. Transesophageal echocardiography can be rapidly used to evaluate for presence of right ventricular dilatation/failure and "right heart strain." In the absence of right heart strain, a clinically significant PE is less likely; with clinically significant right heart strain, right heart failure resulting from MI, PE, and pneumothorax should be under consideration. Treatment of intraoperative PE (systemic anticoagulation vs. directed pharmacologic or mechanical thrombolysis) depends on the clinical symptoms; however, in the presence of hemodynamic instability, elective operations should be terminated.

The etiology of an intraoperative pneumothorax is multifactorial. Interventions leading to pneumothorax include central venous access resulting in iatrogenic lung injury; high ventilator volume/pressure, particularly in patients with mainstem bronchial intubation; diaphragmatic injury; and high insufflation pressures during laparoscopy. For patients with large amounts of intrapleural air, hemodynamic instability may be present when sufficient tension is present that increases mediastinal pressures that impede central venous return. The diagnosis can be made by chest auscultation and/or intraabdominal inspection of the diaphragm. In patients without breath sounds and/or a bulging diaphragm, tube thoracostomy is indicated and should lead to symptomatic improvement. If symptoms have resolved and clinical signs of pneumothorax have been reversed, a surgeon may consider completing the ongoing elective operation.

Hemorrhage

When major vascular injuries occur, rapid blood loss into the operative field can be life threatening and difficult to control. Exposure is immediately compromised, and the next surgical steps should focus on vascular control. If arterial injury is suspected, direct compression and proximal control are frequently the best first steps. Control can often be achieved by compression, proximal vascular isolation and clamping, or a combination of these maneuvers with subsequent vascular repair.

When compression is not possible and/or the major artery cannot be readily dissected, proximal control with supraceliac aortic compression can be achieved quickly by caudal retraction of the stomach, brief mobilization of the left lobe of the liver, division of the gastrohepatic ligament, and compression of the aorta (located just to the left of the esophagus) against the vertebrae. Hands-free control can then be applied by incising the peritoneum, separating the limbs of the right diaphragmatic crus to expose the thoracic aorta, and applying an aortic clamp. These measures facilitate exposure of the vascular injury under a controlled environment and allow anesthesiology colleagues to catch up with resuscitation. Endovascular balloon occlusion of the aorta is also an option for patients with femoral arterial access, and those familiar with this technology often use it in trauma and vascular operations.

In patients with major venous injury, compression of the venotomy combined with direct suture repair is frequently possible. In cases where significant bleeding precludes sufficient visualization of the venotomy, venous compression proximal and distal to the site of injury will help with visualization. Adequate intraoperative exposure and retraction are paramount in any operation. The best preparation for management of vascular injury is sufficient dissection and exposure to allow for management of a vascular injury before hemorrhage and exsanguination.

Under some circumstances, particularly in trauma surgery, multiple sites of bleeding, coagulopathy (from hypothermia, prolonged bleeding, sepsis, or acidosis), and hemodynamic instability can create a scenario in which definitive control of all sites of bleeding may be impossible or impractical. Resuscitation with blood and blood products has been well established in trauma resuscitation[74] and should be used in nontrauma patients with intraoperative hemorrhage; crystalloid should not be used. These patients with intraoperative hemorrhage, clinical instability, and coagulopathy are best served with blood product resuscitation and temporary abdominal packing, followed by ongoing resuscitation in an intensive care setting. Delayed definitive hemostasis can then be achieved under more controlled conditions, either with a return to the operating room or through angiographic embolization.

OUTPATIENT SURGERY

Over recent decades, the volume of operations performed in the outpatient setting has increased dramatically. Driving forces behind this change include improvements in risk assessment and perioperative management, cost differences between outpatient/ambulatory and inpatient/hospital-based care, patient satisfaction, and increased use of ambulatory surgery centers. Ambulatory surgery centers have expanded access to outpatient surgery for patients with suitable operative criteria without associated increases in postoperative mortality or unanticipated admission. Nevertheless, surgeons should determine indications for surgery independent of the operative setting and resist physician-induced demand.[75] Implemented appropriately, outpatient surgery can reduce time away from work and improve patient perception of the postoperative recovery process. However, surgeons and consulting services must exercise caution when selecting patients and cases for the outpatient setting.

The process of preoperative assessment for outpatient surgery should be tailored to the patient and type of operation. In general, only low-risk and some intermediate-risk operations are appropriate in the outpatient setting. Examples include elective orthopedic and plastic operations in patients who will not require postoperative hospitalization, inguinal herniorrhaphy, elective cholecystectomy, superficial excisions, and several head-and-neck and orthopedic operations. Patient risk factors should be assessed preoperatively. For patients with ASA status I to II undergoing low-risk operations, assessments may take place on the day before surgery or even the morning of surgery. Higher-risk patients should undergo assessment in a dedicated preoperative anesthesia clinic, and sufficient time between assessment and day of surgery should be allocated to allow for additional testing, if necessary.

The goals of preoperative evaluation for outpatient surgery are (1) assessment of appropriateness for the outpatient setting, (2) use of direct preoperative testing and risk stratification, and (3) reduction in cancellations on the day of surgery. Preoperative assessment can be performed by a physician, advanced practice provider (NP/PA), nurse, or via standardized questionnaires. Although physician assessments are reliable and comprehensive, they are also the costliest. Conversely, questionnaire assessments are inexpensive but rely on the patient's own perception of health. When nurse- or questionnaire-based assessments are used, reassessment on the day of surgery by either a surgeon or anesthesiologist is advisable. Risk factors associated with unplanned admission or early postoperative mortality in patients selected for an outpatient operation include advanced age, prior recent hospitalization, and invasiveness of the operation.[28]

Certain populations require additional considerations when assessing appropriateness for outpatient surgery. In general, patients with significant cardiopulmonary comorbidity in whom system-specific or other comorbid conditions have not been optimized are not suitable for outpatient surgery. Obese and morbidly obese patients are at increased risk for bronchospasm, hypoventilation, and obstructive airway, but are not strictly prohibited from outpatient operations; however, severe class III obesity with BMI >60 kg/m^2 can be considered an absolute exclusion. Organ system–specific exclusion criteria may include cardiac (unstable angina, at-risk myocardium, cardiomyopathy, moderate to severe heart failure, severe pulmonary hypertension or valvular disease); pulmonary (noncompliant OSA, STOP-BANG ≥ 5 with anticipation for postoperative opioids, severe and poorly controlled asthma, cystic fibrosis, or home oxygen use); hematologic (coagulation disorders requiring postoperative infusion of clotting factors and/or procoagulants); renal (end-stage renal disease and additional organ system dysfunction, too long or too short of an interval between dialysis and operation, uncertain serum potassium or serum potassium >5.5); pregnancy-specific exclusions (complicated pregnancy, fetus >21 weeks' gestation); and other high-risk patient comorbidities (muscular dystrophy, highly contagious airborne infections, e.g., tuberculosis, high risk for hemorrhage, and others). Patients with chronic reflux, difficult airway, or poorly controlled diabetes are at heightened risk of anesthesia-related complications and should be considered for outpatient surgery only at centers with capabilities for postoperative admission.

Patients considered for outpatient surgery should have adequate supportive resources after discharge. After sedation, a patient should not be responsible for transportation home and should have an adult to take them home and be available overnight to provide help if needed. Ideally, emergency care facilities should be readily accessible near the patient's residence should unforeseen complications arise. Absence of these outpatient resources should prompt consideration of elective postoperative hospitalization for observation.

Conclusions

INTRODUCTION OF ANESTHESIOLOGY PRINCIPLES

In 1846, the first public surgery with ether anesthetic heralded the era of modern anesthesiology. Over the next century, the risk of anesthesia-related mortality and morbidity was unacceptably high due to primitive equipment, complication-prone drugs, and lack of adequate monitors.

In recent decades, however, rapid pharmacologic and technologic advances have resulted in the ability to safely provide anesthesia for complex surgical procedures, even in patients with severe underlying disease. Pharmacologic advances include shorter-acting drugs with fewer deleterious side effects. From an equipment standpoint, anesthesia machines now have safety mechanisms to prevent delivery of hypoxic gas mixtures, and their associated ventilators can provide precise and sophisticated respiratory support. Vaporizers for inhalational anesthetics can now deliver reliably accurate doses of these medications. Advanced airway devices can facilitate ventilation and intubation in difficult airway scenarios. Improvements in ultrasound have facilitated the safe and effective execution of peripheral nerve blocks, as well as difficult venous and arterial access, and have shepherded in the use of point-of-care ultrasound for diagnosis and monitoring in the perioperative environment. Other significant improvements in monitoring devices include in-circuit oxygen analyzers, capnometers to assess exhaled carbon dioxide (CO_2), pulse oximeters, and anesthetic vapor-specific analyzers.

This chapter begins with a discussion of foundational anesthetic topics (i.e., the drugs, equipment, and monitors requisite for safe practice) followed by discussion of preanesthetic assessment and preparation for anesthesia, selection of anesthetic techniques and drugs, airway management, conscious sedation, postanesthetic care, and management of acute postoperative pain.

PHARMACOLOGIC PRINCIPLES

Early anesthetic strategy used single drugs—such as ether or chloroform—to achieve all anesthetic end points, including hypnosis, cessation of movement, amnesia, and analgesia. The modern approach is more balanced, using medications along with techniques such as neuraxial or regional anesthesia to achieve anesthetic goals while minimizing the side-effect burden of each intervention. Most anesthesiologists initiate anesthesia with intravenous (IV) medications and maintain it with either inhalational or IV agents supplemented by pain management adjuncts, anxiolytics, and paralytic medications. The high-level benefits and drawbacks to the most used medications in these classes will be explored below.

Inhalational Agents

Inhalational anesthetics pass into the patient's bloodstream at the alveolar-capillary interface and exert their effects on receptors in the central nervous system (CNS). The exact mechanisms are unknown. Volatile anesthetics are liquids at room temperature but can evaporate easily to be delivered in gaseous form. The original volatile anesthetics—ether and chloroform, and nitrous oxide—had important limitations. Ether was characterized by notoriously slow onset and equally delayed emergence but could produce unconsciousness, amnesia, analgesia, and lack of movement without the addition of other agents. Chloroform was associated with hepatic toxicity and, occasionally, fatal cardiac arrhythmias and thus fell out of use.

Subsequent drug development created nontoxic inhalational agents that allow for rapid induction and emergence called *fluorinated ether anesthetics.* Common modern drugs are isoflurane, sevoflurane, and desflurane; halothane and enflurane were commonly used in the past but have largely fallen out of favor in the past one to two decades due to side effects and undesirable pharmacologic properties. The important properties of each volatile anesthetic can be summarized in terms of key clinical attributes (Table 20.1). Of note, in vulnerable patients, volatile anesthetics are triggering agents for the condition malignant hyperthermia (MH), in which sustained skeletal muscle contraction leads to hypermetabolic crisis due to activation of abnormal receptors in the skeletal muscle of vulnerable patients. This condition can lead to severe metabolic acidosis, hyperthermia, rhabdomyolysis, and multisystem organ failure.

Two important measures of inhalational anesthetics are the blood/gas solubility coefficient and the minimum alveolar concentration (MAC). The blood/gas solubility coefficient is a measure of the uptake of an agent by blood. In general, less soluble agents—those with lower blood/gas solubility coefficients—are associated with more rapid induction of and emergence from anesthesia, which include nitrous oxide and desflurane. Agents with high solubility in blood, such as halothane, are associated with relatively slow induction and emergence. Isoflurane and sevoflurane have intermediate rates of induction and emergence. MAC measures the dose of an inhaled anesthetic and is defined as the volume percentage of vaporized agent at which 50% of patients do not move in response to surgical stimulus at normal atmospheric pressure. A higher MAC represents a less potent volatile anesthetic. Among modern volatile agents, halothane is the most potent, with a MAC of 0.75%, whereas desflurane, the least potent of the hydrocarbon-based volatile agents, has a MAC of 6%.

The pungency of anesthetic agents also has practical implications. Agents with low pungency, such as halothane and sevoflurane, do not cause significant airway irritation when delivered at commonly used concentrations and are useful for inhalational induction of anesthesia. This type of induction can allow a patient to maintain spontaneous respiration, which can be beneficial in the case of certain airway and cardiac lesions, and it can be accomplished without IV access, making it a common strategy in pediatric anesthesia. Desflurane is highly irritating to the airways and is not useful for this type of induction. These drugs are all vasodilating, and they can cause dose-dependent myocardial depression.

All inhaled anesthetics can have deleterious effects on the environment. Each can act as a greenhouse gas with direct toxic effects on the ozone layer.[1] Accordingly, judicious use of these agents is advocated during anesthetic management. When exposed to desiccated CO_2 absorbent, the volatile anesthetics are all partially converted to carbon monoxide.[2,3] Because continued gas flow in an unused machine will desiccate the CO_2 absorbent, turning gas flow off in anesthesia machines when they are not in use can reduce carbon monoxide production.

Isoflurane

Approved by the US Food and Drug Administration (FDA) in 1979, isoflurane rapidly replaced halothane as the most used potent inhalational agent. Despite the subsequent release of sevoflurane and desflurane, isoflurane remains commonly used in modern operating rooms, in part because the cost of the now-generic compound is well below that of the newer agents. Its pungent odor virtually precludes use for inhalational induction. Compared with older agents, it causes less reduction in cardiac output, less sensitization to the arrhythmogenic effects of catecholamines, and minimal metabolism (Tables 20.1 and 20.2), but it does cause vasodilation and hypotension in many patients. Isoflurane-induced tachycardia, a variable response, can increase myocardial oxygen consumption. When it is used in patients with coronary artery disease, careful observation

TABLE 20.1 **Important Characteristics of Inhalational Agents**

ANESTHETIC	POTENCY	SPEED OF INDUCTION AND EMERGENCE	SUITABILITY FOR INHALATIONAL INDUCTION	SENSITIZATION TO CATECHOLAMINES	METABOLIZED (%)
Nitrous oxide	Weak	Fast	Insufficient alone	None	Minimal
Isoflurane	Potent	Medium	Not suitable	Minimal	<2
Sevoflurane	Potent	Rapid	Suitable	Minimal	<5
Desflurane	Potent	Rapid	Not suitable	Minimal	0.02
Halothane	Potent	Medium	Suitable	High	≥20
Enflurane	Potent	Medium	Not suitable	Medium	<10
Diethyl ether	Potent	Very slow	Suitable	None	10

TABLE 20.2 **Cardiopulmonary Effects of Inhalational Anesthetics**

INHALATIONAL AGENT	BLOOD PRESSURE	HEART RATE	CARDIAC OUTPUT	SENSITIZATION TO CATECHOLAMINES	VENTILATORY DEPRESSION	BRONCHODILATION
Nitrous oxide	Little effect	Little effect	Little effect	No	Minimal	No
Isoflurane	Moderate dose-dependent decrease	Variable increase	Minimal decrease	Minimal	Marked dose-dependent decrease	Moderate
Sevoflurane	Moderate dose-dependent decrease	Little effect	Moderate dose-dependent decrease	Minimal	Moderate dose-dependent decrease	Moderate
Desflurane	Minimal decrease	Variable; marked increase with rapid increase in concentration	Minimal decrease	Minimal	Marked dose-dependent decrease	Moderate
Halothane	Marked dose-dependent decrease	Moderate decrease	Marked dose-dependent decrease	Marked	Moderate dose-dependent decrease	Moderate
Enflurane	Marked dose-dependent decrease	Moderate decrease	Moderate dose-dependent decrease	Moderate	Moderate dose-dependent decrease	Minimal

and management of the heart rate are necessary. Isoflurane also causes cerebral vasodilation, increasing cerebral blood flow (CBF) and intracranial pressure (ICP); it also depresses cerebral metabolic rate ($CMRO_2$).[4]

Sevoflurane

Sevoflurane's relatively low blood solubility facilitates rapid induction and relatively rapid emergence. Unlike isoflurane, sevoflurane is pleasant to inhale, making it suitable for inhalational induction. It is also a potent bronchodilator, making it useful in maintenance of anesthesia in patients with bronchospastic disease. It, too, causes peripheral vasodilation and thus hypotension, but the cardiac function or conduction effects are not usually clinically significant. Like isoflurane, it can cause cerebral vasodilation and consequent increases in CBF and ICP and decreases in $CMRO_2$.[5]

An often discussed theoretical concern with the use of sevoflurane is the production of compound A, a metabolite produced via the drug's interaction with certain chemicals in the CO_2 absorber of the anesthesia ventilator (i.e., soda lime or Baralyme). Compound A was found to be nephrotoxic in experimental animals. However, there has never been shown to be a clinically significant difference in renal function with use of sevoflurane, so this concern appears to be theoretical. On an animal study level, β-lyase, the enzyme responsible for the formation of compound A, has 8 to 30 times greater activity in rat kidney tissue than in human kidney tissue. Furthermore, many modern CO_2 absorbers do not use soda lime or Baralyme and thus do not produce compound A.[6]

Desflurane

Desflurane is very insoluble and therefore has very quick onset and elimination; there is some evidence that it leads to readier emergence when compared with isoflurane.[7] It has a vapor pressure that makes its boiling point very close to room temperature, so it must be administered through a special vaporizer that heats and pressurizes it to ensure consistent dose delivery. Its pungent odor precludes inhalational induction. Of note, desflurane is associated with tachycardia and hypertension if the inspired concentration is increased too rapidly, but it can also produce dose-dependent vasodilation and hypotension.

Nitrous Oxide

Nitrous oxide is not a volatile anesthetic, as it exists as a gas at normal barometric pressure, but it is administered via inhalation. It has been used for anesthetic purposes for over 150 years and remains popular to this day. It is not a triggering agent for MH. It minimally influences respiration and hemodynamics, and it has a low solubility in blood, giving it rapid onset and emergence properties. However, nitrous has a MAC of 104% at sea level, meaning that it cannot be used alone for maintenance of general anesthesia (it is impossible not to create a hypoxic, or anoxic, gas mixture when approaching a MAC of nitrous). Therefore, it is often combined with one of the potent volatile agents, as MACs of inhaled anesthetics are additive in effect (i.e., 0.5 MAC nitrous + 0.5 MAC sevoflurane = 1 MAC anesthetic) to permit a lower dose of the potent volatile agent, thereby limiting side effects, reducing cost, and facilitating rapid induction and emergence. Although its mechanism is not completely elucidated, it has some *N*-methyl-D-aspartate (NMDA) antagonism and thus some analgesic properties; it is in this context that it is used by laboring parturients.

The most important clinical problem with nitrous oxide is that it is 30 times more soluble than nitrogen and diffuses into closed gas spaces faster than nitrogen diffuses out, thus increasing gas volume and pressure within the closed space. Because of this characteristic, nitrous oxide is contraindicated in the presence of closed gas spaces such as pneumothorax, small bowel obstruction, or middle ear surgery, as well as in retinal surgery in which an intraocular gas bubble is created. It may also be avoided by some anesthesiologists in procedures at risk for venous or arterial air embolism. Because nitrous oxide gradually accumulates in the pneumoperitoneum, some clinicians prefer to avoid its use during laparoscopic procedures. However, periodic venting can prevent gas accumulation.[8]

The Evaluation of Nitrous Oxide in the Gas Mixture for Anesthesia (ENIGMA) Trial, reported in 2007, indicated that patients having major surgical procedures lasting more than 2 hours had a higher incidence of postoperative complications and severe postoperative nausea and vomiting (PONV) if they received 70% nitrous oxide as part of their anesthetic regimen compared with patients randomized to not receive nitrous oxide.[9] However, the more recent ENIGMA II Trial, published in 2014, reported that use of nitrous oxide was not associated with an increased incidence of death, cardiovascular complications, or wound infection in high-risk surgical patients. Although the incidence of severe PONV was higher (15% vs. 11%) in patients receiving nitrous oxide compared with controls, the occurrence of PONV in the nitrous oxide group was effectively controlled by antiemetic prophylaxis,[10] and a subsequent subanalysis demonstrated that there was no difference in PONV rate if exposure was under 1 hour.[11] A 1-year follow-up of ENIGMA II patients did not show an increase in long-term morbidity and mortality with nitrous oxide administration.[12]

Intravenous Agents

IV agents have become an indispensable component of modern anesthetic practice. IV agents are used primarily for induction of anesthesia and as part of multidrug combinations to produce total IV anesthesia (TIVA). IV induction is rapid, pleasant, and safe for most patients; however, there are situations in which IV induction introduces hazards given the properties of available medications. Although several agents can be used for IV induction of anesthesia, propofol is the most widely used agent in the United States. Other agents are summarized in Table 20.3, and the most commonly used agents will be discussed in the following sections.

Propofol

Propofol is a short-acting induction agent that is associated with smooth, nausea-free emergence. The mechanism of action is not fully elucidated but likely involves agonism of γ-aminobutyric acid (GABA) receptors. Small doses are also useful for short-term sedation during brief procedures such as retrobulbar or peribulbar eye blocks, and it is commonly used as a continuous infusion during TIVA and for sedation during less invasive procedures such as gastrointestinal endoscopy or in an intensive care setting.

TIVA generally uses propofol as its mainstay. This anesthetic choice is popular in patients with a history of severe PONV because there is evidence that propofol either as a primary agent or as an adjunct at subhypnotic doses can attenuate PONV, particularly when combined with other antiemetic prophylaxis.[13] Propofol is also a potent bronchodilator. It decreases ICP and $CMRO_2$, so it is often favored in anesthetics for head injury, and it has anticonvulsant properties that may be leveraged when patients are seizing. The primary limitations of propofol are pain on injection, blood pressure reduction, and respiratory depression. Propofol should therefore be used with caution in patients who may be hypovolemic or who may tolerate hypotension poorly, such as those with severe coronary artery disease or severe valvular lesions, and only by individuals trained in airway management in patients without a protected airway. Uncommon side effects include hypertriglyceridemia and pancreatitis with prolonged use as well as the extremely rare but potentially fatal propofol infusion syndrome, which is associated with mitochondrial dysfunction and metabolic acidosis with circulatory collapse.[14]

Ketamine

Ketamine, which produces a dissociative state of anesthesia via NMDA receptor antagonism, is the only IV induction agent that increases blood pressure and heart rate via sympathetic stimulation. Of note, it can also be given as an intramuscular (IM) medication at higher doses to produce similar effects in patients who are acutely agitated or otherwise cannot have IV access established before sedation.

Though cardioexcitatory effects generally dominate, ketamine causes direct cardiac depression that may become evident if given to patients with exhausted sympathetic tone (e.g., hemorrhagic shock). In such a scenario, it may still be used in combination with other induction agents to reduce requirements, and thus the side effects, of any one drug. It is also an excellent bronchodilator. Of the IV induction agents, ketamine causes the least respiratory depression and preserves airway reflexes, which allows for

TABLE 20.3 **Clinical Characteristics of Intravenous (IV) Induction Agents**

IV INDUCTION AGENT	DOSE (MG/KG)	COMMENTS	SIDE EFFECTS	SITUATIONS REQUIRING CAUTION	RELATIVE INDICATIONS
Ketamine	1–2	Psychotropic side effects controllable with benzodiazepines; good bronchodilator; potent analgesic at subinduction doses	Hypertension; tachycardia	Coronary disease; severe hypovolemia	Rapid-sequence induction of asthmatics; patients in shock (reduced doses)
Propofol	1–2	Burns on injection; good bronchodilator; associated with low incidence of postoperative nausea and vomiting	Hypotension	Coronary artery disease; hypovolemia	Induction of outpatients; induction of asthmatics
Etomidate	0.1–0.3	Cardiovascularly stable; burns on injection; spontaneous movement during induction	Adrenal suppression	Hypovolemia	Induction of patients with cardiac contractile dysfunction; induction of patients in shock (reduced doses)
Midazolam	0.15–0.3	Relatively stable hemodynamics; potent amnesia	Synergistic ventilatory depression with opioids	Hypovolemia	Induction of patients with cardiac contractile dysfunction (usually in combination with opioids)

spontaneous breathing even while a patient is fully anesthetized. The drug can, however, induce the production of copious oropharyngeal secretions, so an antimuscarinic agent like glycopyrrolate may be coadministered. Ketamine can theoretically increase ICP, as it increases CBF, so it has been classically avoided in patients with intracranial hemorrhage, although recent data indicate this is of limited functional impact, and ketamine is often used even in patients with traumatic brain injury.

Given its NMDA activity, ketamine is able to produce significant analgesia. It can be used as a sole anesthetic for brief, superficial cases, and it can be a useful adjunct in a balanced anesthetic when given in bolus doses or as an infusion perioperatively. Some patients experience significant dysphoria and nightmares with ketamine, which can be attenuated with a short-acting benzodiazepine given before ketamine administration.

Etomidate

Etomidate is an imidazole compound that produces minimal hemodynamic changes. Because it preserves blood pressure in most patients, etomidate is often chosen as an alternative for induction of patients with cardiovascular disease or severe hypovolemia. It has rapid onset and recovery and does not induce apnea. It also decreases ICP and $CMRO_2$, making it an appropriate choice in head injury. Major drawbacks include burning pain on injection, a high incidence of PONV, abnormal muscular movements (myoclonus), and adrenal suppression via inhibition of 11β-hydroxylase in the cortisol synthesis pathway.[15] There is concern that this adrenal suppression can worsen mortality in critically ill patients when used as an induction agent in that population,[16] but the answer remains unclear, and it remains the subject of significant research. It is unlikely to have deleterious effects when used in a single dose in healthy patients.

Midazolam

Midazolam is a short-acting benzodiazepine that is generally used as an adjunct before induction of general anesthesia given its significant anxiolytic and amnestic properties. It has the potential to cause respiratory depression, particularly when given in conjunction with an opioid, and can occasionally cause paradoxical agitation. In significantly large doses (0.25–0.35 mg/kg) it can be used as an induction agent given its relative cardiovascular stability, but it can lead to prolonged effects. However, its use as an induction agent is rare in modern practice given the superiority of other agents.

Methohexital

Methohexital is an oxybarbiturate that agonizes GABA receptors and inhibits excitatory neurotransmitters with rapid onset and redistribution. It can activate seizure foci, which makes it a preferred induction agent for electroconvulsive therapy. Like many of the other IV agents, it causes vasodilation and respiratory depression, pain on injection, and myoclonus.

Opioids

Opioids are administered to the majority of patients undergoing general anesthesia and to many patients receiving regional or local anesthesia. As a component of a multifaceted anesthetic, opioids produce profound analgesia through agonism of μ receptors as well as minimal cardiac depression. Their disadvantages include ventilatory depression and inconsistent hypnosis and amnesia, which must usually be provided by other agents.

Several reasons explain the popularity of opioids in anesthetic management. First, they provide effective analgesia that can extend through the early postoperative period and can facilitate smoother awakening from anesthesia. Second, they reduce the MAC of potent inhalational agents (i.e., the amount of volatile anesthetic required to prevent a response to surgical stimulus). Third, opioids blunt the hypertension and tachycardia associated with stimulating interventions like endotracheal intubation and surgical incision. Fourth, when administered in doses 10 to 20 times the usual analgesic dose, opioids can act as complete anesthetics in many patients by providing not only analgesia but also hypnosis and amnesia. This characteristic has prompted their use in cardiac surgery patients, rarely as sole anesthetic agents, and much more often as a major component of a multimodal anesthetic. Finally, they are often added to local anesthetic solutions in epidural and intrathecal blocks to improve the quality of analgesia.

Fentanyl is a short-acting synthetic opioid that is commonly used during induction and maintenance of anesthesia. Hydromorphone and morphine are inexpensive, intermediate-acting agents that are commonly used both for maintenance and for postoperative analgesia. There are several other synthetic opioids that are popular intraoperatively. Sufentanil and alfentanil are both potent and lend themselves well to use as infusions during maintenance; their metabolism is relatively rapid but allows enough accumulation to provide short-term postoperative analgesia. Remifentanil, an opioid metabolized by serum esterases, is particularly short acting and does not accumulate during prolonged infusion, making it a useful part of IV anesthetic strategies. There is, however, concern that its use can contribute to hyperalgesia. Methadone is a long-acting opioid that not only acts as a potent μ-opioid receptor agonist but also interacts with NMDA receptors and alters the reuptake of serotonin and norepinephrine in the brain. It has been shown to be an effective and safe option in large, painful procedures like posterior spinal fusion and is gaining popularity in other surgical populations as well,[17] though concerns remain about its prolonged duration of action and variable kinetics in patients with comorbidities that may affect respiratory drive and drug metabolism.

Opioids are not without drawbacks, including PONV, decreased gastric motility, pruritus, the risk for dependence when used in a prolonged manner, and the development of hyperalgesia. Accordingly, there is much ongoing research to determine whether opioid-sparing or even opioid-free anesthetics may have preferable safety profiles while maintaining efficacy in addressing perioperative pain (described further in the following sections). However, a recent 61,249-patient cohort study demonstrated that increased fentanyl and hydromorphone use intraoperatively was associated with less pain and opioid requirement in the postanesthesia care unit (PACU) as well as decreased new chronic pain diagnoses at 3 months, decreased opioid prescriptions at 30/60/180 days, and decreased new persistent use of opioids. It has not yet been elucidated whether this type of effect requires an opioid versus any effective intraoperative analgesic strategy that prevents priming of pain receptors that may contribute to chronic pain.[18]

Neuromuscular Blockers

Paralytic medications allow for a still operating field and improved ability to manipulate muscular tissue to establish satisfactory operating conditions. During intubation, paralysis opens the vocal cords, allowing smooth passage of an endotracheal tube into the trachea. Before the advent of modern neuromuscular blocking drugs, these conditions were approximated by significantly increasing the dose of volatile anesthetic past what was necessary just to provide hypnosis and amnesia, leading to an increased risk of hypotension and other deleterious anesthetic side effects.

The two categories of neuromuscular blockers in clinical use are depolarizing (noncompetitive) and nondepolarizing (competitive) agents. The depolarizing agents exert agonistic effects at the cholinergic receptors of the neuromuscular junction, initially causing contractions evident as fasciculations followed by an interval of profound relaxation. The nondepolarizing class of drugs competes for receptor sites with acetylcholine in the neuromuscular junction and prevents depolarization, with the magnitude of block dependent on the availability of acetylcholine, the concentration of neuromuscular blocker in the neuromuscular junction, and the affinity of the agent for the receptor.

Succinylcholine, the only depolarizing agent still in clinical use, remains popular for endotracheal intubation because of its rapid onset and short duration of action when given as a bolus dose. The drug is rapidly metabolized by plasma pseudocholinesterase, except in a small fraction of patients with atypical or absent pseudocholinesterase. At intubating doses, onset of muscle relaxation is rapid (45–60 seconds), which facilitates intubation in patients at risk for aspiration. Because neuromuscular function begins to recover after about 3 minutes, a patient who cannot be successfully intubated can be ventilated by mask for a short time until spontaneous respiration resumes. However, a patient who cannot be ventilated by mask after succinylcholine administration will likely not resume spontaneous breathing before the onset of life-threatening hypoxemia. Of note, succinylcholine can also be given IM, which may be required if a patient has laryngospasm (involuntary closure of the vocal cords that can lead to severe hypoxemia) during inhalational induction or other situations in which IV access is not present or functional. Succinylcholine is not suitable for longer-term muscle relaxation during surgery, as very high cumulative doses can lead to prolonged paralysis that is not predictable in duration or reversibility and is known as phase II blockade, the mechanism of which is outside the scope of this chapter. If this occurs, the patient must be monitored and kept sedated pending recovery of strength.

Although it is extremely useful, succinylcholine is also associated with serious hazards in a small proportion of patients. It can result in severe, life-threatening hyperkalemia in patients with burns, paraplegia, and quadriplegia, as these patients express abnormal extrajunctional acetylcholine receptors that release large amounts of intracellular potassium when activated by the drug. When given alone or when combined with a volatile agent, it is also implicated in triggering MH in susceptible individuals. Therefore, it is best avoided in patients at risk for MH, including those with muscular dystrophy or a family history of MH. It can also cause severe bradycardia, particularly in children, via stimulation of muscarinic receptors at the sinus node. Because succinylcholine causes visible muscle fasciculations, it has been implicated in causing postoperative myalgias. There is ongoing investigation as to whether or not pretreatment with a small dose of a nondepolarizing agent (a “defasciculating” dose) can reduce this side effect.

Several nondepolarizing neuromuscular blockers are currently available, each with advantages and disadvantages. These drugs can be used for intubation and for intraoperative maintenance of muscle relaxation. The choice of drug is generally related to desired kinetics and clearance, with attention to side effects, especially if older drugs are used. Doses required to provide satisfactory operating conditions are summarized in Table 20.4. Rocuronium is an intermediate-acting drug (30–45 minutes effect for a standard dose) that produces intubating conditions within 3 minutes when administered at the appropriate dose. It is cleared primarily by biliary excretion, with a small amount of renal clearance as well. When the intubation dose is doubled, intubating conditions can be reached within 45 seconds, allowing for a rapid sequence intubation without the drawbacks of succinylcholine. This does increase the duration of effect significantly, which can pose difficulties in a cannot intubate–cannot ventilate situation. Vecuronium has similar characteristics to rocuronium but a longer onset time and higher potency. Cisatracurium is another intermediate-acting drug. Its major advantage is that it is eliminated via enzymatic degradation in the plasma, also known as Hofmann elimination, making its kinetics extremely predictable, even when given as an infusion or in patients with hepatic or renal dysfunction.

Dosing of nondepolarizing agents requires knowledge of several important characteristics. First, the use of neuromuscular blockers prevents movement in response to noxious stimuli. Therefore, chemical paralysis can mask the signs of inadequate anesthesia intraoperatively. Medicolegal claims of intraoperative awareness during general anesthesia are more than twice as frequent in patients receiving intraoperative muscle relaxants. Second, higher doses are required to provide satisfactory conditions for intubation than for surgical relaxation. Therefore, if a nondepolarizer is used only after intubation, smaller doses are required. Third, other anesthetic drugs potentiate the actions of nondepolarizing agents. Succinylcholine used for intubation decreases subsequent requirements for nondepolarizers. Potent inhalational

TABLE 20.4 **Dose-Response Relationships of Nondepolarizing Neuromuscular Blocking Drugs in Humans**

DRUG	DURATION	ED_{50} (MG/KG)	ED_{95} (MG/KG)	INTUBATING DOSE (MG/KG)
Rocuronium	Intermediate	0.147 (0.069–0.220)	0.305 (0.257–0.521)	0.6–1.0
Cisatracurium	Intermediate	0.026 (0.15–0.31)	0.04 (0.32–0.55)	0.15–0.2
Vecuronium	Intermediate	0.027 (0.015–0.031)	0.043 (0.037–0.059)	0.1–0.2
Mivacurium	Short	0.039 (0.027–0.052)	0.067 (0.045–0.081)	0.15–0.2
Pancuronium	Long	0.036 (0.022–0.042)	0.067 (0.059–0.080)	0.08–0.12
Tubocurarine	Long	0.23 (0.16–0.26)	0.48 (0.34–0.56)	0.5–0.6

Data are mean (95% confidence limits). Somewhat larger doses are required to facilitate endotracheal intubation.

ED_{50}, Dose effective for surgical relaxation in 50% of patients; ED_{95}, dose effective for surgical relaxation in 95% of patients.

Modified from Naguib M, Lien CA. Pharmacology of muscle relaxants and their antagonists. In: Miller RD, Fleisher LA, Johns RA, et al, eds. *Miller's Anesthesia*. 6th ed. Philadelphia: Churchill Livingstone; 2005:481-572.

agents dose dependently potentiate the effects of competitive neuromuscular blockers. The newer inhalational agent desflurane potentiates the effects of vecuronium approximately 20% more than isoflurane. Fourth, individual responses to muscle relaxants vary widely, with patients demonstrating both markedly increased and markedly decreased neuromuscular blockade compared with expected levels.

Fifth, and most important, subtle blockade can be difficult to detect and can be associated with postoperative complications. The importance of subtle residual paralysis has recently been quantified using the train-of-four (TOF) fade ratio, a semiquantitative monitoring technique that can assess the depth of neuromuscular blockade and the adequacy of pharmacologic reversal. To determine this ratio, four electrical pulses are delivered to a nerve at 0.5-second intervals, and a muscle twitch is monitored to determine the strength of contraction with each stimulus. The gold standard monitoring location is the ulnar nerve, with expected response at the adductor pollicis muscle. When a patient is fully paralyzed, there are no twitches elicited with stimulation, as the acetylcholine receptors are saturated with drug, so acetylcholine cannot bind. As the drug is metabolized and/or cleared, twitches return. The TOF quantifies the magnitude of the fourth twitch compared with the first twitch. At the conclusion of anesthesia, a TOF ratio greater than 0.90 has been considered adequate return of neuromuscular function. Residual neuromuscular blockade results in an increased incidence of postoperative pulmonary complications, with severity ranging from mild hypoxia to reintubation and ICU admission. Of note, clinical signs of strength such as head lift and hand grip are inferior to quantitative monitoring in assessing function, and normal tidal volumes can be achieved by an intubated patient even with significant levels of neuromuscular blockade due to recovery of diaphragm function before recovery of other muscle groups required to protect the airway after extubation.[19]

Return of neuromuscular function can be prompted by administration of reversal agents. Historically, nondepolarizing relaxants are pharmacologically reversed with an anticholinesterase (neostigmine or edrophonium) accompanied by atropine or glycopyrrolate to counteract the muscarinic effects of the anticholinesterase (bradycardia, gastrointestinal effects). This makes additional acetylcholine available to compete to agonize the receptor. The ability to achieve effective competition depends on the depth of neuromuscular blockade at the time of reversal and on the dose of reversal administered. If blockade is too dense, the patient cannot be reversed in this manner, and the anesthesiologist has to wait until twitches return. Peak reversal can take up to 15 minutes even when appropriately dosed. Complete reversal must be assessed by quantitative TOF to safely extubate.

The development of sugammadex has overcome many of the problems associated with using anticholinesterases to reverse neuromuscular blockade. Sugammadex is a cyclodextrin that directly binds nondepolarizing steroidal neuromuscular blocking agents such as rocuronium and vecuronium (i.e., it cannot reverse cisatracurium). Sugammadex rapidly reverses neuromuscular blockade and avoids the muscarinic side effects associated with use of anticholinesterases. Dosing of sugammadex is based on the depth of neuromuscular blockade. Therefore, monitoring of blockade depth with a twitch monitor is required for optimal reversal of neuromuscular blockade even with sugammadex. Nevertheless, a comparison of sugammadex to neostigmine for reversal of neuromuscular blockade in patients undergoing abdominal surgery showed that sugammadex administration eliminated residual neuromuscular blockade in the PACU and shortened the time of readiness for discharge from the operating room.[20]

ANESTHESIA MACHINE

Anesthesia equipment has undergone rapid development in recent decades. The central piece of equipment for delivery of anesthesia is the modern anesthesia machine. The anesthesia machine functions primarily to deliver respiratory support and volatile anesthetics to the patient. In addition, modern anesthesia machines have sophisticated ventilators that allow for effective respiratory support and have integrated monitors that accurately measure oxygen delivery, inspired and end-tidal gas concentrations, airway pressures, minute ventilation, and fresh gas flows.

The essential elements of an anesthesia machine are gas sources (oxygen, nitrous oxide, and air), flow meters, and a flow-proportioning device. In most cases, gases are delivered to the anesthesia machine from a bank of large H cylinders housed in a central area within the hospital. A backup system of E cylinders is attached directly to the anesthesia machine and provides a source of gases, particularly oxygen, if the central gas source becomes unavailable. The flow meters allow independent administration of individual gases. To minimize the chance of delivering a hypoxic gas mixture, anesthesia machines feature so-called fail-safe valves that require pressurization of the oxygen line before nitrous oxide can be delivered and flow-proportioning devices that automatically reduce the flow of nitrous oxide if the flow of oxygen is reduced below a safe concentration. The measurement of inspired oxygen concentration provides a further safeguard against delivering hypoxic gas mixtures.

The anesthesia machine also integrates vaporizers that are able to deliver exact doses of volatile anesthetic as specified by the anesthesia provider. The aforementioned monitoring equipment also allows for close tracking of inhaled and expired concentrations of these gasses so that depth of anesthesia can be gauged.

PATIENT MONITORING DURING AND AFTER ANESTHESIA

Effective monitoring is a critical aspect of anesthesia care. The essential components of monitoring include observation and vigilance, instrumentation, data analysis, and institution of corrective measures, if indicated. The goal of patient monitoring is to provide optimal anesthetic management and to detect physiologic abnormalities early in their course so that corrective measures can be instituted before serious or irreversible injury occurs. Although it is difficult to directly relate improved patient outcomes with specific monitors, the reduction in anesthesia-related morbidity and mortality has paralleled the institution of current monitoring practices.

The indications as well as risks and benefits associated with the use of noninvasive and invasive electronic monitors must be assessed for each individual patient (Box 20.1). These decisions are guided by the patient's medical condition, the type of surgery, and the potential complications associated with invasive monitoring. However, the proliferation of electronic monitoring devices does not circumvent the need for clinical skills such as observation, inspection, auscultation, and palpation. The American Society of Anesthesiologists (ASA) has established standards for basic anesthetic monitoring that were most recently updated in 2020.[21] These standards are designed to integrate clinical skills and electronic monitoring with the goal of enhancing patient safety.

BOX 20.1 Routine and Specialized Electronic Monitors Used in Anesthetic Practice and Their Indications

Routine Monitors

- Pulse oximetry
  - Blood oxygen saturation
  - Heart rate
  - Tissue perfusion (via plethysmography)
- Automated blood pressure cuff
  - Blood pressure
- Electrocardiogram (ECG)
  - Heart rhythm
  - Heart rate
  - Monitor of myocardial ischemia
- Capnography
  - Adequacy of ventilation
  - Intratracheal placement of endotracheal tube
  - Pulmonary perfusion
- Oxygen analyzer
  - Monitoring of delivered oxygen concentration
- Ventilator pressure monitor
  - Ventilator disconnection during general anesthesia
  - Monitoring of airway pressure
- Temperature monitoring

Specialized Monitors

- Monitoring of urine output (Foley catheter)
  - Gross indicator of intravascular volume status and renal perfusion
- Arterial catheter
  - Continuous measurement of arterial blood pressure
  - Sampling of arterial blood
- Central venous catheter
  - Continuous measurement of central venous pressure
  - Delivery of centrally acting drugs
  - Rapid administration of fluids and blood
- Pulmonary artery catheter
  - Measurement of pulmonary artery pressure
  - Measurement of left ventricular pressure
  - Measurement of cardiac output
  - Measurement of mixed venous oxygenation
- Precordial Doppler
  - Detection of air embolism
- Transesophageal echocardiography
  - Evaluation of myocardial performance
  - Assessment of heart valve function
  - Assessment of intravascular volume
  - Detection of air embolism
- Esophageal Doppler
  - Assessment of descending aortic blood flow
  - Assessment of cardiac preload
- Transpulmonary indicator dilution
  - Measurement of cardiac output
  - Measurement of preload
- Esophageal and precordial stethoscope
  - Auscultation of breathing and heart sounds
- Processed electroencephalogram (EEG; SedLine or bispectral index [BIS])
  - Depth of anesthesia

Standard I asserts that a qualified anesthesia care provider must be continuously present in the operating room during the administration of anesthesia. The practitioner must continuously monitor the status of the patient and alter anesthesia care based on the patient's response to the dynamic changes associated with anesthesia and surgery.

Standard II mandates continual assessment of oxygenation, ventilation, circulation, and temperature during all anesthetics. Specific requirements include the following:

- Oxygenation:
  - The use of an oxygen analyzer with a low-oxygen–concentration alarm during general anesthesia
  - Employment of quantitative assessment of blood oxygenation, such as by pulse oximetry
- Ventilation:
  - Continual clinical evaluation to assess the adequacy of ventilation, with quantitative monitoring of expired CO_2 when procedural or patient factors allow
  - Verification of endotracheal tube/laryngeal mask placement by both clinical assessment and monitors that identify the presence of CO_2 in expired gases
  - A device capable of detecting disconnection of breathing system components during mechanical ventilation that can give an audible signal when its alarm threshold is exceeded
- Circulation:
  - Electrocardiogram (ECG) monitoring from induction until departure from the anesthetizing location
  - Heart rate and blood pressure evaluation at least every 5 minutes
  - Another means of assessing circulatory function, including pulse plethysmography or oximetry, palpation, continuously monitored electronic means, or auscultation
- Temperature:
  - Ready availability of means of temperature evaluation during periods of intended or expected changes in body temperature

Oxygenation Monitoring

Monitoring the fractional concentration of oxygen in inspired gas (FiO_2) and hemoglobin oxygen saturation is a standard of care during all general anesthetics. Modern anesthesia machines are equipped with oxygen analyzers that detect the delivered oxygen concentration (FiO_2). This monitor, in combination with fail-safe devices, low-oxygen delivery alarms, and oxygen ratio monitors, greatly decreases the chance of delivering a hypoxic gas mixture during anesthesia.

Pulse oximetry capitalizes upon the fact that oxygenated and deoxygenated blood absorb and reflect different amounts of red and infrared light. Pulse oximeters send signals of both wavelengths through the patient's tissue, and a receiver determines the absorbed and reflected amounts and determines a percent saturation. These devices are fairly accurate over a saturation of 80%, but one has to be aware of a number of common sources of artifact and inaccuracy. Dark skin colors, dense nail polish, bright ambient light (e.g., operating room lights), and poor perfusion to the digit can all impact the accuracy of the monitor.

Ventilation Monitoring

The sedative hypnotic and analgesic agents used for deep sedation and/or general anesthesia can depress or abolish spontaneous ventilation, necessitating intraoperative ventilatory support. Several means are available to assess the adequacy of ventilation, among which are physical assessment of chest expansion, auscultation of breath sounds, and evaluation for evidence of upper airway obstruction and stridor. Precordial and esophageal stethoscopes provide continuous input regarding air movement and the development of wheezing. During mechanical ventilation, monitors of airway pressure and minute ventilation alert the anesthesiologist to conditions that can impair ventilation, such as disconnection of the ventilatory circuit, dislodgement of the endotracheal tube, obstruction of the gas delivery system, and changes in airway resistance or compliance, or both. These are gross assessments, however, and tools exist to be more exact.

The advent of end-tidal CO_2 ($ETCO_2$) monitoring has greatly enhanced precision and accuracy of this assessment. $ETCO_2$ can be monitored via specialized nasal cannula in patients who are spontaneously breathing and via expired gas analysis in those who are intubated or have a laryngeal mask airway (LMA) in place. In patients with normal cardiopulmonary physiology, the difference between $ETCO_2$ in and $PaCO_2$ is 2 to 5 mm Hg in a closed system. The gradient between end-tidal and arterial CO_2 reflects dead space ventilation, which is increased in cases of decreased pulmonary blood flow, such as pulmonary air embolism or thromboembolism and decreased cardiac output. Therefore, $ETCO_2$ monitoring can also provide important information regarding systemic perfusion. Specifically, $ETCO_2$ will decrease during periods of decreased cardiac output and pulmonary perfusion.

Blood Pressure Monitoring

Blood pressure monitoring is required during all anesthetics. Noninvasive blood pressure monitoring is appropriate for the majority of surgical cases, and most modern operating rooms are equipped with automated oscillometric blood pressure analyzers. Indications for invasive blood pressure monitoring with arterial catheters include anticipation of wide perioperative blood pressure swings, the need for multiple blood gas analyses or other labs, the need for continuous blood pressure monitoring in patients with significant end-organ dysfunction or those having high-risk surgical procedures, and the inadequacy of noninvasive blood pressure measurements (e.g., morbidly obese patients with irregularly shaped limbs or patients with left ventricular assist devices who lack a pulse).

Several sites for arterial cannulation are available, each with inherent advantages and potential for complications. The radial artery is most commonly cannulated because of its superficial location, relative ease of access, and in most patients, adequate collateral flow from the ulnar artery. Other potential sites for percutaneous arterial cannulation include the femoral, brachial, axillary, ulnar, dorsalis pedis, and posterior tibial arteries. Possible complications of intraarterial monitoring include hematoma, neurologic injury, arterial thrombus, limb ischemia, infection, and inadvertent intraarterial injection of drugs. Intraarterial catheters are not placed in extremities with potential vascular insufficiency. However, with proper patient selection, the complication rate associated with intraarterial cannulation is low and its benefits can be important.

Electrocardiography

ECG monitoring is a standard of care during the administration of anesthesia. Information regarding dysrhythmias and cardiac ischemia can be readily obtained from ECG data. Analysis of ECG tracings is also the cornerstone of cardiopulmonary resuscitation protocols.

Temperature Monitoring

Temperature is monitored in all patients undergoing general anesthesia. The site of measurement is dependent on the surgical procedure and the physical characteristics of the patient. Esophageal temperature is most commonly measured during general anesthesia, as it reflects core temperature. Other common sites of temperature monitoring include nasopharynx, bladder (via Foley catheter), axillary, cutaneous, rectal, tympanic membrane, and, in patients with pulmonary artery catheters (PACs), the pulmonary artery. Because of the potential morbidity associated with hypothermia and hyperthermia, it is important to monitor body temperature and institute measures to maintain temperature as close to normal as possible.

Neuromuscular Blockade Monitoring

Because of variability in sensitivity to and metabolism of neuromuscular blockers, it is essential to monitor neuromuscular function in patients receiving paralytics. The most common sites of monitoring are at the ulnar or facial nerves, with the former being the gold standard. The basis of neuromuscular monitoring is assessment of muscle activity after proximal nerve stimulation (Box 20.2), as previously described. This evaluation gives an indication of acetylcholine receptor blockade at the neuromuscular junction. The degree of neuromuscular blockade is indicated by a decreased evoked response to twitch stimulation. As noted earlier in this chapter, it is essential to monitor neuromuscular blockade and to assure resolution of blockade at the end of anesthesia to minimize the incidence of postoperative complications related to residual neuromuscular blockade.

BOX 20.2 Techniques for Assessing Neuromuscular Blockade

Train-of-Four: Four Successive 200-μs Stimuli Over a 2-second Period

- Twitch height progressively fades with increasing blockade.
    - Loss of the fourth twitch indicates 75% receptor blockade.
    - Loss of the third twitch indicates 80% blockade.
    - Loss of the second twitch indicates 90% blockade.
    - Loss of the first twitch indicates 100% blockade.
    - Clinical relaxation requires 75% to 95% blockade.
- Presence of four twitches without fade suggests adequate reversal of neuromuscular blockade.
- Use of accelerometry provides a quantitative comparison of the first and fourth twitches of the train-of-four (TOF) and generates a TOF (ratio of the fourth twitch over the first twitch), with a TOF <0.9 signifying clinically significant residual blockade.

Double-Burst Stimulation: Two Successive Sets of 50-Hz Bursts (Three Stimuli/Burst) Separated by 750 ms (Appears as Two Twitches)

- Easier to detect fade visually with this technique than with TOF.
- Loss of the second twitch indicates 80% receptor blockade.
- Presence of two twitches without fade suggests adequate reversal of neuromuscular blockade.

Tetany: Sustained 50-Hz or 100-Hz Burst

- Duration of sustained contraction fades with increasing blockade.
- Sustained contraction for 5 seconds suggests adequate reversal of neuromuscular blockade.

Central Nervous System Monitoring

Awareness during anesthesia is an uncommon, but disturbing, complication that occurs when a patient is not adequately anesthetized for the level of stimulus. The risk is highest in procedures during which significant hemodynamic instability or urgency may preclude appropriate dosing of anesthetics (i.e., traumas, cardiac surgery, emergency cesarean sections) or when TIVA is used because the dose-response curve is less consistent than that of inhaled anesthetics, and it is possible to have an unrecognized loss of IV access during a procedure. Lack of cortical arousal cannot be ensured by hemodynamic monitoring, as there can be a discordance between sympathetic response to stimulus and awareness of that stimulus. It also cannot be definitively determined by assessing movement, as a patient may have reflexive movements without cortical function (spinal reflexes are not necessarily extinguished by hypnotic agents), and in patients who are paralyzed, movement cannot be used as a sign.

Processed electroencephalogram (EEG) can directly help anesthesiologists characterize the intraoperative cortical function. There are two commercially available systems in use: SedLine, which analyzes the spatial and temporal gradients of EEG frequency bands, and the bispectral index (BIS), which analyzes the phase and power of EEG bands via a proprietary algorithm. Both produce an indexed number between 0 and 100 that is a surrogate for the depth of sedation, with a lower number representing suppression of brain activity and 100 representing an awake patient. These monitors function well to represent the depth of anesthesia.[22] Compared with end-tidal MAC monitoring when volatile anesthetics are used, these monitors have not been shown to be superior in preventing awareness,[23] but they have shown to be beneficial in preventing awareness in TIVA.[24] Processed EEG can also help prevent anesthetic overdose by allowing clinicians to decrease sedation when cortical activity is completely suppressed and address other physiologic changes directly. There is ongoing work to determine whether this type of adjustment has the potential to decrease postoperative cognitive dysfunction (POCD) and delirium. Although burst suppression on EEG under anesthesia does correlate with delirium,[25] it remains unclear if avoiding burst suppression prevents the development of POCD or delirium postoperatively.[26,27]

Advanced Hemodynamic Monitoring

Measuring cardiac output during surgical procedures can be necessary in critically ill patients or patients with severe comorbid conditions. There exist numerous modern noninvasive cardiac output monitors that use pulse wave analysis of the arterial waveform[28] and several that use finger cuffs to calculate these quantities.[29] The gold standard for these measurements remains thermodilution with a PAC. PACs and even central venous pressure monitoring via central venous catheter are no longer ubiquitous in the operating room, as numerous studies failed to demonstrate an advantage to their use, and some even suggested adverse outcomes.[30] However, in patients with heart failure or pulmonary hypertension, many anesthesiologists and surgeons still find these devices useful. Transesophageal echocardiography (TEE) plays a major role in cardiac surgery, both for monitoring and diagnostic purposes. It has found its role outside the cardiac operating rooms as well in helping to identify occult pathology and as an aid in the rescue and guidance of management for patients in shock.[31]

Point-of-Care Ultrasound

Emergency medicine physicians and trauma surgeons have been early adopters of point-of-care ultrasound with the implementation of focused assessment with sonography in trauma (FAST). Anesthesiologists have also adopted the use of point-of-care ultrasound throughout the perioperative space. The use of ultrasound in the preoperative clinic and just before surgery led to a significant impact to avoid delays for further workup and, in remote cases, identification of occult pathology that changed the trajectory of management for these patients.[32] The use of ultrasound in the operating room has found a niche for multiple facets in the care of surgical patients to include confirmation of the airway, assessment of the cardiac[33] and pulmonary systems,[34] and identification of gastric contents before surgery.[35] In some cases, the use of ultrasound has also had an impact on survival for those in septic shock.[36]

ANESTHESIOLOGY PERSPECTIVES ON PREOPERATIVE EVALUATION

The ASA has established basic standards for preanesthetic care: an anesthesiologist is required to evaluate the medical status of the patient, derive a plan for anesthetic care, and discuss the plan with the patient. The Joint Commission requires that all patients receiving anesthesia undergo a preanesthetic evaluation. Traditionally, these preanesthetic evaluations occurred in close proximity to surgical intervention as a means of identifying medical conditions necessitating special consideration when prescribing the anesthetic plan. However, over the past few decades, technologic advancements in both the surgical and anesthetic spheres have allowed surgical operations to be offered to patients with increasing medical complexity. Additionally, the understanding of factors associated with increased perioperative risk has significantly increased to include healthcare, patient, and socioeconomic characteristics. This combination has spurred a rise in preoperative clinics as a means of identifying high-risk patients, intervening upon modifiable risk factors, and optimizing medical comorbidities to improve perioperative outcomes and decrease healthcare costs. Optimally, preoperative clinics need to stratify patients into low and high-risk categories and provide efficient, predictable, and thorough evaluations for both groups. Although high-risk patients may require these visits to occur in person, possibly weeks in advance of their operations to allow for optimization, low-risk patients without complicated medical problems who are scheduled for elective, low-risk procedures may be interviewed by telephone or virtually before surgery and given preoperative instructions.

The anesthesia preoperative evaluation serves multiple purposes. First, it allows the patient an opportunity to speak to an anesthesiologist and discuss the expected impact of anesthesia, including the patient's fears and concerns regarding anesthesia and postoperative pain management. Second, the preanesthetic interview focuses on the type of surgery, the underlying conditions necessitating surgery, any history of previous anesthetics, and the presence of coexisting diseases. The preoperative interview allows evaluation of the patient's medical status to determine whether additional medical evaluation or treatment is needed before surgery. This process requires a focused history, physical examination, and, if indicated, laboratory evaluation. Current medications must be reviewed to anticipate potential drug interactions and manage medical problems during the perioperative period. Instructions regarding oral intake, changes in medication use, and other important issues that need to be addressed before surgery are communicated to the patient during the preoperative interview.

A well-focused history allows the practitioner to perform targeted physical and laboratory examinations. Laboratory testing should be tailored toward patient- and surgery-specific conditions. Healthy patients undergoing elective procedures may not need preoperative laboratory testing. The use of routine preoperative testing, especially in asymptomatic healthy patients, is costly with poor yield in both diagnostic and prognostic information. False-positive tests can cause needless delays in surgery and could require follow-up, increasing costs and potentially leading to harm or injury associated with further tests and procedures. However, targeted testing based on results of the history and physical exam can significantly improve overall patient care.

Investigation of conditions associated with increased perioperative morbidity is important for reducing the risks related to anesthesia and surgery. Coexisting conditions that must be carefully evaluated include intravascular volume status, airway abnormalities, cardiovascular disease, pulmonary disease, neurologic disease, renal and hepatic disease, and disorders of nutrition, endocrinology, and metabolism. Preoperative pregnancy testing is controversial. The rationale for performing preoperative pregnancy testing is the potential for spontaneous abortion and birth anomalies associated with surgery and anesthesia. Currently, anesthetic agents used in standard clinical dosing and duration have not been shown to have any teratogenic effects in humans, and a paucity of literature exists regarding adverse neurodevelopmental effects of anesthetic agents on the fetus.[37] A clear sexual history and documentation of the last menstrual cycle are obtained in females of childbearing age. In ambiguous situations, a preoperative pregnancy test is indicated; however, informed consent for preprocedural pregnancy testing including risks, benefits, and alternatives should be obtained.

Airway Examination

Assessing the airway is a crucial step in developing an anesthetic plan. Even if regional anesthesia is planned, general anesthesia and the need to maintain a patent airway could be necessary in the advent of failed block, surgical needs, or complications. The goal of the airway examination is to identify characteristics that could hinder assisted mask ventilation or tracheal intubation. A history of diseases or conditions that are associated with airway closure or difficult laryngoscopy will alert the practitioner to potential airway difficulties. Review of previous anesthetic records can provide invaluable information regarding previous airway management. The airway examination is completed by systematic inspection of the mouth opening, thyromental distance, neck mobility, ability to protrude the jaw (should be able to bite upper vermillion border with bottom teeth), and the size of the tongue in relation to the oral cavity (Box 20.3). The patient is observed in both frontal and profile views because many airway abnormalities, such as a recessed mandible, will not be evident from a frontal view. The size of the tongue in relation to the oral cavity can be graded by using the Mallampati classification (Fig. 20.1). The Mallampati examination is performed with the patient sitting and the head in a neutral position, the mouth opened as wide as possible, and the tongue protruded maximally. The observer views the oral and pharyngeal structures that are evident. In general, a patient in whom the uvula, tonsillar pillars, and soft palate are visible (class I) will be easy to mask ventilate and intubate. Patients in whom only the hard palate is visible, a class IV airway, have a higher likelihood of being difficult to mask ventilate and intubate. However, the Mallampati classification is only one component of the airway examination and must be used in conjunction with other aspects of the airway examination and the patient's history to provide a complete airway assessment. Other physical factors that are associated with uncomplicated airway management are adequate mouth opening, neck extension, and thyromental distance. In a meta-analysis examining more than 30,000 patients, Detsky and coauthors[38] reported that while

BOX 20.3 Important Factors in Performing an Airway Examination

Patient History

- Previous anesthetic history
- Medical history (e.g., history of oropharyngeal mass, pharyngeal disease)
- Review of the chart to assess prior airway management during previous anesthetics

Physical Examination

- Mouth opening (should be 6–8 cm [three to four fingerbreadths])
- Cervical spine mobility
- Mallampati classification
- Thyromental distance (should be 6–8 cm [three to four fingerbreadths])
- Ability to protrude the jaw (should be able to bite upper vermillion border with bottom teeth)
- Frontal and profile view
- Neck circumference
- Assessment for disease-associated airway abnormalities
- Presence of facial hair

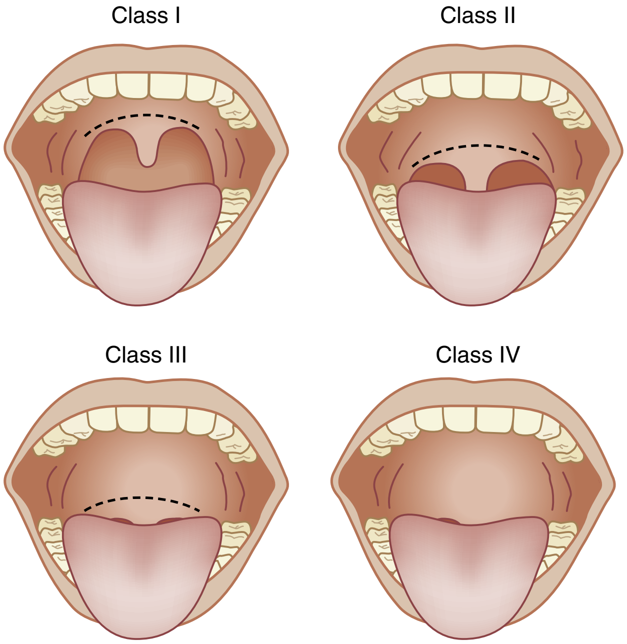

FIGURE 20.1 The Mallampati classification relates tongue size to pharyngeal size. This test is performed with the patient in the sitting position, the head held in a neutral position, the mouth wide open, and the tongue protruding to the maximum. The subsequent classification is assigned according to the pharyngeal structures that are visible: class I, visualization of the soft palate, fauces, uvula, and anterior and posterior pillars; class II, visualization of the soft palate, fauces, and uvula; class III, visualization of the soft palate and the base of the uvula; and class IV, soft palate not visible at all. (From Mallampati SR, Gatt SP, Gugino LD, et al. A clinical sign to predict difficult tracheal intubation: a prospective study. *Can Anaesth Soc J.* 1985;32:429-434.)

clinical findings are useful predictors for a higher likelihood of difficult intubation, clinical findings alone cannot reliably exclude a difficult intubation. However, inability to bite the upper lip with the lower teeth most significantly increases the probability of difficult intubation.

Cardiovascular Disease

The risk for perioperative myocardial ischemia and infarction and the risk for cardiac death have become important issues as surgery is offered to patients with increasingly severe systemic disease and as more children with congenital cardiac anomalies are surviving later into adulthood. As reviewed in Chapter 19, the American College of Cardiology (ACC) and American Heart Association (AHA) have published guidelines for perioperative cardiovascular evaluation and management of patients undergoing noncardiac surgery that were most recently revised in 2014.[39]

Functional status is a reliable predictor of perioperative and long-term cardiovascular risk. Historically, in the absence of recent exercise testing, a patient's functional status was assessed based on determination of ability to perform common activities and functional capacity is commonly expressed in terms of metabolic equivalents of the task (METs), where 1 MET is the resting or basal oxygen consumption of a 40-year-old, 70-kg male. Perioperative cardiac and long-term risks are increased in patients unable to perform 4 METs of work during daily activities, which correlates to being able to climb a flight of stairs or walking up a hill. Although functional capacity had traditionally been determined on a subjective basis during the perioperative interview, assessment tools such as the Duke Activity Status Index (DASI) have been found to be superior to subjective assessment in predicting postoperative mortality and myocardial infarction within 30 days.[40] This tool has a maximum score of 58.2, with different levels of activity conferring different points (e.g., walking one to two blocks on level ground is 2.75 points, whereas strenuous physical activities such as singles tennis is 7.5 points). With this scale, a score less than 34 signifies a patient at increased risk for cardiac morbidity and mortality in the perioperative period, and a score less than 25 represents the highest risk of major adverse cardiac events and moderate to severe postoperative complications.[41] The clinician must consider the urgency of surgery, the patient's functional capacity, and type of surgery, giving these factors appropriate weight. Since publication of the perioperative cardiovascular evaluation guidelines in 2002 and the revisions in 2007 and 2014, several new randomized trials and cohort studies have suggested modifications to the algorithm, particularly around the utilization of the DASI versus METs assessment.

The need for specific testing is dependent on the patient's exercise tolerance, comorbidities, and the type of surgery proposed. Box 20.4 defines current recommendations on specific perioperative testing including preoperative electrocardiography, echocardiography, stress testing, radionuclide perfusion scans, and coronary angiography. It is recommended that practitioners refer to the most recent ACC/AHA guidelines for detailed recommendations and level of evidence to support the guidelines.[39]

Perioperative medical management is guided by the patient's cardiovascular status, current drug regimen, and the type of surgery proposed. The need for preoperative coronary revascularization is limited to patients who are candidates for emergency or urgent revascularization under any circumstances. Such patients include those with unstable angina, active myocardial infarction, or arrhythmias caused by active ischemia. Elective coronary revascularization to decrease perioperative cardiovascular complications in most patients undergoing noncardiac surgery is not supported by current evidence. Recommendations for management of patients who have undergone recent coronary revascularization are presented in Fig. 20.2.

Currently, the ACC/AHA recommends continuation of β-blocker therapy in those patients who are on chronic β-blocker therapy.[21] In β-blocker–naïve patients, perioperative β-blocker

BOX 20.4 Summary of Recommendations for Supplemental Preoperative Evaluation

The 12-Lead ECG

- Preoperative resting 12-lead ECG is reasonable for patients with known coronary heart disease or other significant structural heart disease, except for low-risk surgery.
- Preoperative resting 12-lead ECG may be considered for asymptomatic patients, except for low-risk surgery.
- Routine preoperative resting 12-lead ECG is not useful for asymptomatic patients undergoing low-risk surgical procedures.

Assessment of LV Function

- It is reasonable for patients with dyspnea of unknown origin to undergo preoperative evaluation of LV function.
- It is reasonable for patients with heart failure with worsening dyspnea or other change in clinical status to undergo preoperative evaluation of LV function.
- Reassessment of LV function in clinically stable patients may be considered.
- Routine preoperative evaluation of LV function is not recommended.
- Exercise stress testing for myocardial ischemia and functional capacity.
- For patients with elevated risk and excellent functional capacity, it is reasonable to forgo further exercise testing and proceed to surgery.
- For patients with elevated risk and unknown functional capacity, it may be reasonable to perform exercise testing to assess for functional capacity if it will change management.
- For patients with elevated risk and moderate to good functional capacity, it may be reasonable to forgo further exercise testing and proceed to surgery.
- For patients with elevated risk and poor or unknown functional capacity, it may be reasonable to perform exercise testing with cardiac imaging to assess for myocardial ischemia.
- Routine screening with noninvasive stress testing is not useful for low-risk noncardiac surgery.

Cardiopulmonary Exercise Testing

- Cardiopulmonary exercise testing may be considered for patients undergoing elevated risk procedures.

Noninvasive Pharmacologic Stress Testing Before Noncardiac Surgery

- It is reasonable for patients at elevated risk for noncardiac surgery with poor functional capacity to undergo either DSE or MPI if it will change management.
- Routine screening with noninvasive stress testing is not useful for low-risk noncardiac surgery.

Preoperative Coronary Angiography

- Routine preoperative coronary angiography is not recommended.

therapy should be initiated with caution and based on clinical judgment. However, recent studies show that new initiation of β-blockade within 60 days of surgery may not carry an increased risk of perioperative stroke as was previously thought.[42] Similarly, the perioperative use of calcium channel blockers should be based on patient comorbidities and clinical judgment. Statins should be continued in patients on chronic statin therapy. Perioperative initiation of statin therapy should be considered in patients undergoing vascular surgery and patients at risk for cardiovascular disease who are undergoing high risk procedures. The use of α_2-agonists for prevention of cardiac events is not recommended, based on the current literature. Some controversy exists around whether to hold angiotensin-converting enzyme inhibitors and angiotensin receptor antagonists 24 hours before surgery. A prospective cohort trial by Roshanov and colleagues (VISION study) demonstrated withholding these medications before surgery was associated with a lower risk of death and postoperative vascular events.[43] However, Hollmann et al. in their subsequent meta-analysis did not confirm this observation, although they did confirm the increased incidence of intraoperative hypotension with continuing these drugs throughout the perioperative period.[44] An overview of recommendations for perioperative medical management is provided in Box 20.5.

Endocarditis Prophylaxis

Some patients with congenital or valvular heart disease are at increased risk for infective endocarditis (IE). Previous guidelines that recommended prophylactic antibiotics for at-risk patients undergoing dental, urinary, gastrointestinal, or respiratory surgical procedures were significantly scaled back by the AHA in 2007[39] when it was determined that IE was more attributable to intermittent bacteremia caused by daily activities (e.g., toothbrushing) than by dental and surgical procedures. This guidance was confirmed in a recent review by Wilson and colleagues[45];

BOX 20.5 Summary of Recommendations for Perioperative Medical Management

Coronary Revascularization Before Noncardiac Surgery

- Revascularization before noncardiac surgery is recommended when indicated by existing clinical practice guidelines.
- Coronary revascularization is not recommended before noncardiac surgery exclusively to reduce perioperative cardiac events.

Timing of Elective Noncardiac Surgery in Patients With Previous PCI

- Noncardiac surgery should be delayed after PCI, 14 days after balloon angioplasty and 30 days after BMS implantation.
- Noncardiac surgery should be delayed 365 days after DES implantation.
- A consensus decision as to the relative risks of discontinuation or continuation of antiplatelet therapy can be useful.
- Elective noncardiac surgery after DES implantation may be considered after 180 days, though some newer stents may allow a shorter interval.
- Elective noncardiac surgery should not be performed in patients in whom DAPT would need to be discontinued perioperatively within 30 days after BMS implantation or within 12 months after DES implantation, though some newer stents may allow a shorter interval.
- Elective noncardiac surgery should not be performed within 14 days of balloon angioplasty in patients in whom aspirin will need to be discontinued perioperatively.

Perioperative β-Blocker Therapy

- β-Blockers should be continued in patients who are on long-term β-blocker therapy.
- Management of β-blockers after surgery should be guided by clinical circumstances.
- In patients with intermediate-risk or high-risk preoperative test results, it may be reasonable to begin β-blocker therapy.
- In patients with three or more RCRI factors, it may be reasonable to begin β-blockers before surgery.
- Initiating β-blockers in the perioperative setting as an approach to reduce perioperative risk is of uncertain benefit in those with a long-term indication but no other RCRI risk factors.
- It may be reasonable to begin perioperative β-blockers long enough in advance to assess safety and tolerability, preferably >1 day before surgery.
- β-Blocker therapy should not be started on the day of surgery.

Perioperative Statin Therapy

- Continue statins in patients currently taking statins.
- Perioperative initiation of statin use is reasonable in patients undergoing vascular surgery.
- Perioperative initiation of statins may be considered in patients with a clinical risk factor who are undergoing elevated-risk procedures.

α_2-Agonists

- α_2-Agonists are not recommended for prevention of cardiac events.

Angiotensin-Converting Enzyme (ACE) Inhibitors

- Continuation of ACE inhibitors or angiotensin receptor blockers (ARBs) is reasonable perioperatively.
- If ACE inhibitors or ARBs are held before surgery, it is reasonable to restart as soon as clinically feasible postoperatively.

Antiplatelet Agents

- DAPT is continued in patients undergoing urgent noncardiac surgery in the first 4–6 weeks after BMS or DES implantation, unless the risk of bleeding outweighs the benefit of stent thrombosis prevention.
- In patients with stents undergoing surgery that requires discontinuation P2Y12 inhibitors, continue aspirin and restart the P2Y12 platelet receptor-inhibitor as soon as possible after surgery.
- Management of perioperative antiplatelet therapy should be determined by consensus of treating clinicians and the patient.
- In patients undergoing nonemergency/nonurgent noncardiac surgery without prior coronary stenting, it may be reasonable to continue aspirin when the risk of increased cardiac events outweighs the risk of increased bleeding.
- Initiation or continuation of aspirin is not beneficial in patients undergoing elective noncardiac noncarotid surgery who have not had a previous coronary stent.

Perioperative Management of Patients With CIEDs

- Patients with ICDs should be on a cardiac monitor continuously during the entire period of inactivation, and external defibrillation equipment should be available. Ensure that ICDs are reprogrammed to active therapy.

BMS, Bare metal stent; *CIED,* cardiac implantable electrical device; *DAPT,* dual antiplatelet therapy; *DES,* drug-eluting stent; *ICD,* implantable cardioverter-defibrillator; *PCI,* percutaneous coronary intervention; *RCRI,* revised cardiac risk index.

Adapted from Fleisher LA, Fleischmann KE, Auerbach AD, et al. 2014 ACC/AHA guideline on perioperative cardiovascular evaluation and management of patients undergoing noncardiac surgery: a report of the American College of Cardiology/American Heart Association Task Force on practice guidelines. *J Am Coll Cardiol.* 2014;64:e77-e137.

therefore, antibiotic prophylaxis is recommended for only four categories of patients thought to have the highest risk of adverse outcomes (Box 20.6). In these patients, the AHA panel states that antibiotic prophylaxis is recommended for dental procedures that involve manipulation of gingival tissues, periapical region of teeth, or perforation of oral mucosa as well as respiratory tract procedures or procedures that manipulate infected skin or musculoskeletal structures. Antibiotics for IE prophylaxis are no longer recommended for genitourinary or gastrointestinal tract procedures. Oral amoxicillin is the drug of choice, and alternative drugs and routes are recommended for patients who are unable to take oral medications or those with penicillin allergy (Table 20.5).

Pulmonary Disease

Many surgical patients have obstructive or restrictive pulmonary disease. The preoperative history focuses on functional status, exercise tolerance, severity of respiratory disease, and current medications. The recent trajectory of symptoms must be closely evaluated. A thorough chest physical examination must be performed. These factors guide preoperative testing, which may include chest radiography, arterial blood gas analysis, and pulmonary function testing. The goal of preoperative evaluation is to detect and treat reversible pulmonary pathology, optimize medical management, and allow planning for postoperative ventilatory support, if indicated.

The perioperative risk associated with preexisting pulmonary disease has been extensively studied. As described in Chapter 19, the most commonly used and validated tool in predicting postoperative pulmonary complications is the Assess Respiratory Risk in Surgical Patients in Catalonia (ARISCAT) score. Obstructive sleep apnea (OSA) is an increasingly common condition in surgical patients that also requires preoperative evaluation and optimization.

BOX 20.6 Cardiac Conditions Associated With the Highest Risk of Adverse Outcome From Endocarditis for Which Prophylaxis With Dental Procedures is Reasonable

- Prosthetic cardiac valve or prosthetic material used for cardiac valve repair
- Previous, relapsed, or recurrent infective endocarditis (IE)
- Congenital heart disease (CHD)[a]
  - Unrepaired cyanotic CHD, including palliative shunts and conduits
  - Completely repaired congenital heart defect with prosthetic material or device, whether placed by surgery or by catheter intervention, during the first 6 months after the procedure[b]
  - Repaired CHD with residual defects at the site or adjacent to the site of a prosthetic patch or prosthetic device (which inhibit endothelialization)
- Cardiac transplantation recipients who develop cardiac valvulopathy

[a] Except for the conditions listed above, antibiotic prophylaxis is no longer recommended for any other form of CHD.

[b] Prophylaxis is reasonable because endothelialization of prosthetic material occurs within 6 months after the procedure.

The ASA, Society for Ambulatory Anesthesia, and Society of Anesthesia and Sleep Medicine have released practice guidelines for the management of patients with OSA.[46–48] These guidelines emphasize the importance of preoperative identification of patients at increased risk from OSA, which can be accomplished with the use of validated screening tools such as the STOP-BANG questionnaire and the ASA checklist.[49] Currently, in the absence of concomitant uncontrolled systemic comorbidities such as cardiopulmonary disease, delay of surgical procedures for further investigation and diagnosis is not recommended. Finally, these guidelines emphasize the development of protocols to optimize perioperative care of patients with OSA that may include minimizing sedating medications and instituting postoperative use of positive airway pressure devices, particularly in the immediate postoperative period.

Patients with asthma or chronic obstructive pulmonary disease should be examined and evaluated for bronchodilator and steroid use, number and severity of recent respiratory exacerbations, history of previous intubation, and precipitating factors. Preoperative optimization is driven by patient symptomatology and encompasses smoking cessation, optimization of pharmacologic therapies including inhaled β_2-agonists, anticholinergics, and steroids, and treating other existing comorbidities such as malnutrition. The choice of anesthetic agents and technique is dependent on patient condition and type of surgery. In patients with active disease, elective surgery should be postponed until the patient is adequately treated.

Pulmonary function testing in the preoperative period remains controversial, except in patients undergoing major lung resection or who are found to have new, unexplained dyspnea. Pulmonary function testing has variable predictive value, cannot define a threshold above which the risk associated with surgery is prohibitive, and cannot identify patients at risk who do not already have clinical evidence of pulmonary disease. Arterial blood gas analysis also does not identify a group for whom the risk of surgery is prohibitive, but it may provide an informative baseline of a patient's overall respiratory status and accelerative intraoperative and postoperative decisions and comfort for extubation of patients with baseline chronic hypoxia and/or chronic hypercarbia. Spirometry may be helpful in a patient who has unexplained cough, dyspnea, or exercise intolerance, or if there is a question regarding optimal improvement of airflow obstruction.

Renal and Hepatic Disease

Patients with acute renal or hepatic insufficiency should not undergo elective surgery until these conditions can be adequately characterized and stabilized.

Chronic renal insufficiency (CRI) provides many perioperative management challenges, including acid-base abnormalities, electrolyte disturbances, and coagulation disorders. Current daily urinary output in patients making urine and the type/frequency of dialysis, dialysis access, and any related complications should be established. Physical examination should evaluate volume status as well as evaluate for CRI-complications, including coagulopathy, anemia, pericardial effusion, and encephalopathy. Laboratory evaluation includes assessment of anemia, electrolyte abnormalities (particularly hyperkalemia and acidemia), and coagulopathy. Dialysis ideally should be performed 18 to 24 hours before surgery to avoid the fluid and electrolyte shifts that occur immediately after dialysis.

Chronic liver disease poses many perioperative challenges, with increasing risk conferred by severity of dysfunction. Liver disease can alter drug metabolism, and hypoalbuminemia increases the free fraction of many drugs, impacting pharmacokinetics and dynamics of anesthetics. Altered synthetic function can also lead to coagulopathy and hypercoagulability. Patients with elevated portal pressures may

TABLE 20.5 Antibiotic Regimens for Dental Procedures

		REGIMEN (SINGLE DOSE ADMINISTERED 30–60 MIN BEFORE THE PROCEDURE)	
SITUATION	**AGENT**	**ADULTS**	**CHILDREN**
Able to take oral medication	Amoxicillin	2 g	50 mg/kg
Unable to take oral medication	Ampicillin	2 g IM or IV	50 mg/kg IM or IV
	Cefazolin or ceftriaxone	1 g IM or IV	50 mg/kg IM or IV
Allergic to penicillin or ampicillin	Cephalexin	2 g	50 mg/kg
	Clindamycin	600 mg	20 mg/kg
	Azithromycin or clarithromycin	500 mg	15 mg/kg
Allergic to penicillin or ampicillin and unable to take oral medication	Cefazolin or ceftriaxone	1 g IM or IV	50 mg/kg IM or IV
	Clindamycin	600 mg IM or IV	20 mg/kg IM or IV

Cephalosporins should not be used in an individual with a history of anaphylaxis, angioedema, or urticaria with penicillins or ampicillin.
IM, Intramuscular; *IV*, intravenous.

also have encephalopathy and ascites, which can impact medication doses and increase risk for aspiration, respectively.

Endocrinology, Metabolism, and Nutrition

Diabetes mellitus is prevalent in the surgical population, and there is a clear association between hyperglycemia and adverse clinical outcomes. Preanesthetic evaluation should include the type of diabetes, the current medication regimen, and any sequelae of disease, including autonomic dysfunction, cardiovascular disease, renal insufficiency, retinopathy, and neurologic complications. Patients with poorly controlled diabetes are at high risk for delayed gastric emptying and gastroesophageal reflux, which can predispose aspiration. Perioperative management of glucose requires careful attention, given the risks of both hypoglycemia and hyperglycemia. Over the long term, there is compelling evidence of a correlation between hyperglycemia and increased perioperative complications and decreased long-term survival. An A1c <8% is a commonly accepted target before elective surgeries. During a surgical encounter, there is evidence that treating hyperglycemia (>180 mg/dL) reduces complications and mortality.[50] In diabetic patients undergoing surgery, several principles of management are generally accepted. Current recommendations for diabetes medication management are as follows:

1. Insulin pumps should be continued at sleep basal rates.
2. Provide a reduced dose of intermediate-acting or long-acting insulin and hold short-acting insulin on the morning of surgery.
3. Once a diabetic who is receiving nothing by mouth is given insulin, provide glucose in IV fluids or closely monitor plasma glucose concentrations.
4. Plasma glucose concentrations should be checked before surgery and before discharge as a minimum.
5. In patients with type 2 diabetes, most authors suggest holding oral antidiabetic medications and noninsulin injectables on the day of surgery. Metformin is usually stopped because of a slight risk for perioperative drug-induced lactic acidosis.
6. Perioperative insulin requirements vary depending on body weight, liver disease, steroid therapy, infection, and the use of cardiopulmonary bypass.

As described in Chapter 19 (Figure 19.7), Patients who are receiving systemic glucocorticoids at a dose equivalent of 5 mg of prednisone daily for at least 2 weeks during the month before surgery may have adrenal insufficiency and be unable to respond adequately to surgical stress without glucocorticoid supplementation. Appropriate dosing is based on the duration of therapy and the type of surgery.

Malnutrition affects a large portion of patients undergoing major surgery and is associated with multiple adverse outcomes including postoperative morbidity, mortality, infection, poor wound healing, prolonged hospitalization, and delirium. Malnutrition risk should be evaluated in patients preoperatively using a validated malnutrition screening tool such as the perioperative nutrition screen (PONS), and patients should be supplemented with oral protein where appropriate.[51]

Fasting Before Surgery

Pulmonary aspiration of gastric contents during anesthesia is an uncommon, but serious, complication. To minimize the risk of large volume aspiration, nil per os (NPO; nothing by mouth) guidelines have been developed. Traditionally, orders for "NPO after midnight" forbade any intake of liquids and solids starting at midnight of the day of surgery. However, applying the same guidelines for clear liquids (gastric emptying time of 1–2 hours) and solids (gastric emptying time of 6 hours) has been questioned. The ASA guidelines (first adopted in 1998 and most recently updated in 2017) recommend a minimum fasting period of 2 hours after the ingestion of clear liquids; 4 hours after the ingestion of breast milk; 6 hours for light, nonfatty solids (e.g., toast) and nonclear liquids such as infant formula, milk, or orange juice; and 8 hours for heavier foods (Table 20.6). *Clear liquids* are defined as liquids that one can see through that do not contain solids or particulates. The routine use of gastrointestinal stimulants, gastric acid secretion blockers, antacids, and antiemetics is not recommended. However, many patients have medical conditions or take medications that cause decreased gastric emptying, which may warrant use of promotility or antacid medications. When these guidelines cannot be met during emergency procedures, other precautions such as rapid sequence intubation are utilized to decrease the risk of aspiration.

TABLE 20.6 Summary of Preoperative Fasting Recommendations to Reduce the Risk of Pulmonary Aspiration[a]

INGESTED MATERIAL	MINIMUM FASTING PERIOD (HOURS)
Clear liquids[b]	2
Breast milk	4
Infant formula	6
Nonhuman milk	6
Light, nonfatty solid food	6
All other food	8

[a] Applies to healthy patients undergoing elective procedures.

[b] Examples of clear liquids are water, fruit juices without pulp, black coffee, clear tea, and carbonated beverages.

Adapted from Practice guidelines for preoperative fasting and the use of pharmacologic agents to reduce the risk of pulmonary aspiration: application to healthy patients undergoing elective procedures: a report by the American Society of Anesthesiologist Task Force on Preoperative Fasting. *Anesthesiology.* 1999;90:896-905.

The reported incidence of aspiration during general anesthesia is 1 in every 2000 to 3000 cases. A higher incidence has been noted during emergency surgery and in patients with disease processes that slow gastric emptying. Of note, some reports suggest that aspiration is at least as common during emergence from anesthesia as during the induction phase. Of patients in whom aspiration is suspected, fewer than half exhibit evidence of pulmonary injury. In one study, approximately one-third of patients with suspected aspiration during anesthesia required postoperative intubation and ventilation. Most of these patients were extubated within 6 hours of surgery. About 10% of patients required intubation and ventilation for 24 hours or longer. Approximately half the patients requiring ventilation for longer than 24 hours after aspiration of gastric contents died of pulmonary complications.

Assessment of Physical Status

As covered in Chapter 19 (Table 19.1), the ASA has developed a graded, descriptive scale to categorize preoperative comorbidity. The classification is independent of operative procedure and serves as a standardized method of communicating patient physical status to anesthesiologists and other healthcare providers.

Selection of Anesthetic Techniques and Drugs

Patient factors (e.g., comorbidities and home medications) and surgical factors both influence choice of anesthetic technique and choice of drugs. For example, operative site, positioning, and surgical duration are surgical factors that impact airway management and medication management. Expected disposition (home vs. admission) may influence factors such as appropriateness of neuraxial analgesia or choice of opioid. After completing the preanesthetic evaluation and understanding surgical needs, the anesthesiologist discusses various options regarding anesthetic care with the patient, and, ideally, a joint decision is made about approach if multiple options exist.

The major categories of anesthetic approach include monitored anesthesia care (sometimes abbreviated as MAC, to be distinguished from the identical abbreviation for minimum alveolar concentration), regional anesthesia with or without additional sedation (including regional upper and lower extremity blocks, subarachnoid blocks, and epidural anesthesia), and general anesthesia. MAC generally requires that analgesia be provided via local anesthetic delivered by the surgeon or via regional techniques performed by the anesthesia team, as sedation must be light enough that patients are able to maintain spontaneous ventilation. The target depth of sedation—be it anxiolysis alone with a responsive patient or a patient who is sedated enough to require repeated or painful stimulation to respond purposefully—should be determined intentionally based on the needs of the patient and surgical procedure. Regional techniques can allow for a fully awake patient (e.g., parturient during cesarean section under spinal, or a carotid endarterectomy under superficial and deep cervical plexus blocks) or can be supplemented with MAC or even a general anesthetic should the block be intended primarily for postoperative analgesia. The ability to convert a lighter anesthetic to a general anesthetic should procedural or patient factors require doing so must be anticipated. These approaches will be discussed at greater length in the following sections.

Risk of Anesthesia

Patients often desire information regarding the risk of death or major complications associated with anesthesia. Because perioperative death and major complications have become relatively uncommon, the risk associated with anesthesia is difficult to quantify. An estimated 313 million surgical cases occur worldwide each year. In developed nations, surgical mortality is estimated to be 0.4% to 3.7%, with morbidity rates of 6.7% to 13.8%.[52] The risk for cardiac arrest attributable to anesthesia appears to be less than 1 in 10,000 cases.[53] The American College of Surgeons National Surgical Quality Improvement Program (ACS NSQIP) risk calculator (http://www.surgicalriskcalculator.com) is a validated tool that can be used to predict patient-specific risks and help inform surgical and anesthetic decision-making and informed consent.[54] The ACS NSQIP risk calculator incorporates 20 patient predictors including age, sex, functional status, ASA physical status class, body mass index, chronic medical conditions, surgical procedure, and urgency of the procedure to predict the likelihood of 18 different outcomes within 30 days following surgery. However, this tool does not consider anesthetic technique, which may modify the overall risk.

Because so many surgical procedures are now performed without admission to the hospital, understanding the risk associated with ambulatory anesthesia is particularly important. Large studies have repeatedly demonstrated low rates of morbidity and mortality after ambulatory surgery. Patient and procedure selection as well as social factors (e.g., availability of a responsible individual to take the patient home) are important in determining the safety of outpatient anesthesia and surgical procedures.[55]

AIRWAY MANAGEMENT

Airway management is perhaps one of the most critical skills in anesthesiology. As previously discussed, the preoperative evaluation focuses on recognition of patients who may be difficult to mask ventilate or intubate. Knowledge of and skill with various techniques for establishing an airway are central to the safe practice of anesthesiology. Fortunately, the incidence of difficult intubations is low. Difficult direct laryngoscopy occurs in 1.5% to 8.5% of general anesthetics, and failed intubation occurs in 0.13% to 0.3% of general anesthetics. The LMA, the lighted stylet, and an array of video laryngoscopes are recent developments that make ventilation and intubation possible in many patients who would have failed intubation with a conventional laryngoscope. The fiberoptic bronchoscope is an additional tool for the management of a difficult airway.

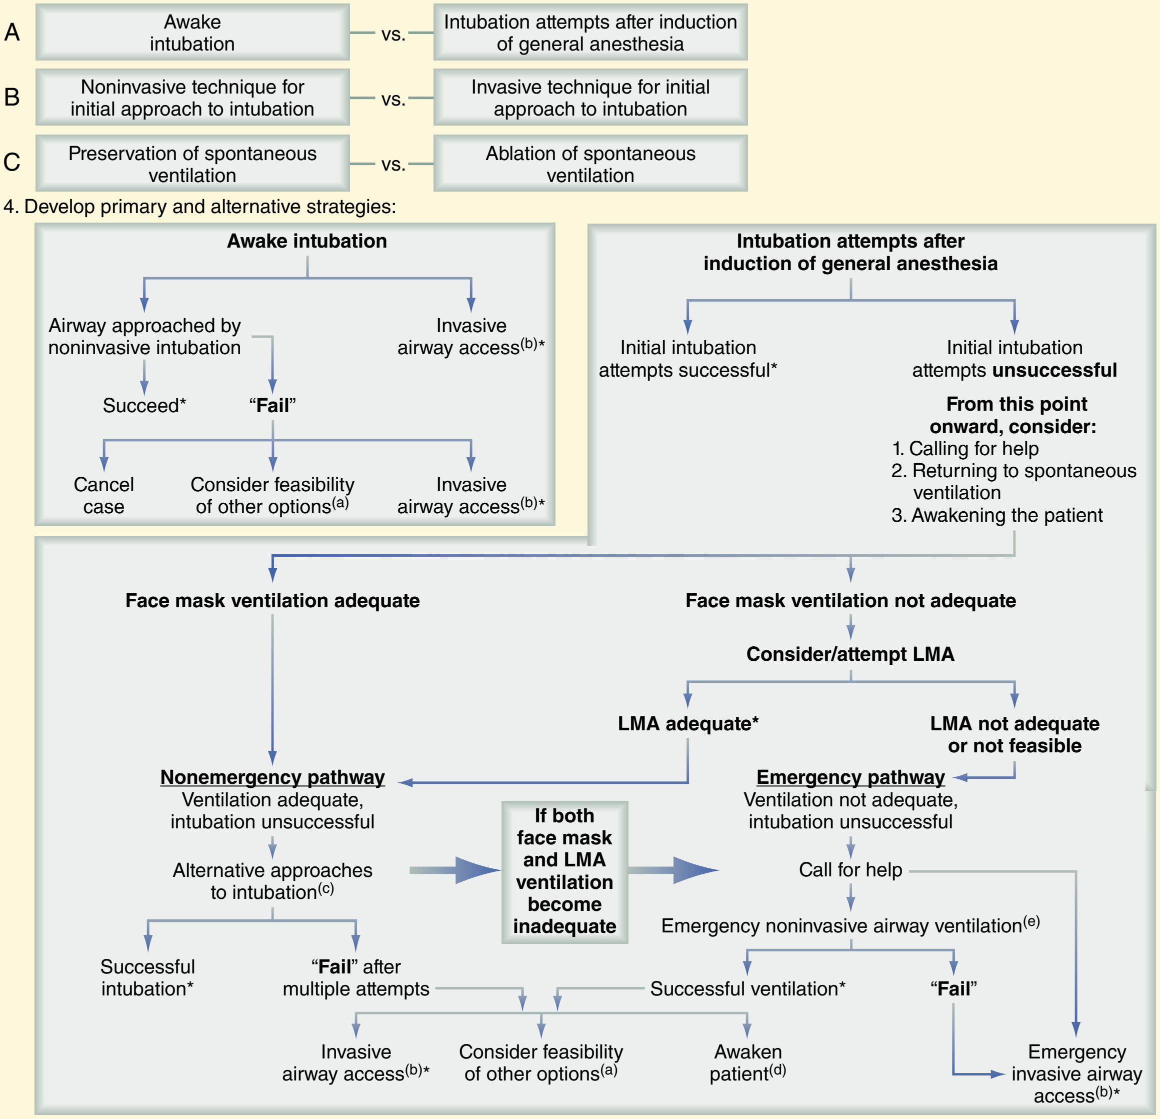
Given the importance of a prompt, effective response to difficult intubation, the ASA has developed guidelines for managing difficult airways (Fig. 20.3). A key factor is the recognition of the patient with a potentially difficult airway. If the practitioner suspects that mask ventilation and tracheal intubation will be difficult, it is recommended that spontaneous ventilation be preserved. Approaches to these patients include awake intubation or the use of anesthetic techniques that preserve spontaneous ventilation. In some cases, establishment of a surgical airway in an awake patient under local anesthesia may be indicated. However, some patients are found to have a difficult airway only after anesthesia and muscle relaxation have been induced. This is an emergency situation that must be addressed quickly to avoid hypoxemia, brain injury, or death. A variety of airway adjuncts are available to preserve ventilation and facilitate tracheal intubation under emergency conditions. The practitioner should call for assistance in these situations to optimize patient safety and consider reestablishment of spontaneous ventilation. It is essential to have alternate means for securing the airway available for all patients in the event of an unanticipated difficult airway.

GENERAL ANESTHESIA

General anesthesia is a reversible state of unconsciousness. Although the mechanism of general anesthetics remains speculative and controversial, the four components of general anesthesia (i.e., amnesia, analgesia, inhibition of noxious reflexes, and skeletal muscle relaxation) are usually achieved in modern anesthesia by a combination of IV anesthetics and analgesics, inhalational anesthetics, and, frequently, muscle relaxants. Because the drugs that produce these components cause both desirable and undesirable physiologic changes, the pharmacologic effects of the agents must be matched to the pathophysiology of the patient's comorbidities. The major adverse changes associated with anesthetic drugs are respiratory depression, cardiovascular depression, and loss of airway maintenance and protection. Important complications of general anesthesia include hypoxemia with possible CNS damage; hypotension; cardiac arrest; and aspiration of acidic gastric contents, which can lead to severe pulmonary damage. Dental damage is more frequent but not life-threatening. General anesthesia can be maintained by inhalation of volatile agents or by infusion of IV agents. Both techniques can have advantages under certain conditions, and individual patient factors should be considered. Discussion of specific agents occurred earlier in this chapter (see the section "Pharmacologic Principles"). General anesthesia is required for major intraabdominal and thoracic

DIFFICULT AIRWAY ALGORITHM

1. Access the likelihood and clinical impact of basic management problems:
   - A. Difficult ventilation
   - B. Difficult intubation
   - C. Difficulty with patient cooperation or consent
   - D. Difficult tracheostomy
2. Actively pursue opportunities to deliver supplemental oxygen throughout the process of difficult airway management
3. Consider the relative merits and feasibility of basic management choices:



A
Awake intubation
vs.
Intubation attempts after induction of general anesthesia
B
Noninvasive technique for initial approach to intubation
vs.
Invasive technique for initial approach to intubation
C
Preservation of spontaneous ventilation
vs.
Ablation of spontaneous ventilation
4. Develop primary and alternative strategies:
Awake intubation
Airway approached by noninvasive intubation
Invasive airway access(b)*
Succeed*
"Fail"
Cancel case
Consider feasibility of other options(a)
Invasive airway access(b)*
Intubation attempts after induction of general anesthesia
Initial intubation attempts successful*
Initial intubation attempts unsuccessful
From this point onward, consider:
1. Calling for help
2. Returning to spontaneous ventilation
3. Awakening the patient
Face mask ventilation adequate
Face mask ventilation not adequate
Consider/attempt LMA
LMA adequate*
LMA not adequate or not feasible
Nonemergency pathway
Ventilation adequate, intubation unsuccessful
Alternative approaches to intubation(c)
If both face mask and LMA ventilation become inadequate
Emergency pathway
Ventilation not adequate, intubation unsuccessful
Call for help
Emergency noninvasive airway ventilation(e)
Successful intubation*
"Fail" after multiple attempts
Successful ventilation*
"Fail"
Invasive airway access(b)*
Consider feasibility of other options(a)
Awaken patient(d)
Emergency invasive airway access(b)*

***Confirm ventilation, tracheal intubation, or LMA placement with exhaled CO_2**

a. Other options include (but are not limited to): surgery utilizing face mask or LMA anesthesia, local anesthesia infiltration, or regional nerve blockade. Pursuit of these options usually implies that mask ventilation will not be problematic. Therefore, these options may be of limited value if this step in the algorithm has been reached via the Emergency Pathway.

b. Invasive airway access includes surgical or percutaneous tracheostomy or cricothyrotomy.

c. Alternative noninvasive approaches to difficult intubation include (but are not limited to): use of different laryngoscope blades, LMA as an intubation conduit (with or without fiberoptic guidance), fiberoptic intubation, intubating stylet or tube changer, light wand, retrograde intubation, and blind oral or nasal intubation.

d. Consider repreparation of the patient for awake intubation or canceling surgery.

e. Options for emergency noninvasive airway ventilation include (but are not limited to): rigid bronchoscope, esophageal-tracheal combitube ventilation, or transtracheal jet ventilation.

FIGURE 20.3 American Society of Anesthesiologists difficult airway algorithm. The likelihood and clinical impact of basic management problems such as difficult intubation, difficult mask ventilation, and difficulty with patient cooperation or consent should be assessed in all patients in whom airway management is being contemplated. The clinician should consider the relative merits and feasibility of basic management choices, including the use of awake intubation techniques, preservation of spontaneous ventilation, and the use of surgical approaches to establish a secure airway. Primary and alternative strategies should be considered: (a) other options include, but are not limited to, surgery under mask anesthesia, surgery under local infiltration or nerve block, and intubation attempts after induction of general anesthesia; (b) alternative approaches include the use of different laryngoscope blades, awake intubation, blind oral or nasal intubation, fiberoptic intubation, an intubating stylet or tube changer, light wand, retrograde intubation, and surgical airway access; (c) see awake intubation; (d) options for an emergency nonsurgical airway include transtracheal jet ventilation, laryngeal mask airway *(LMA),* and Combitube. (From Practice guidelines for management of the difficult airway. A report by the American Society of Anesthesiologists Task Force on Management of the Difficult Airway. *Anesthesiology*. 1993;78:597-602.)

procedures, most neurosurgical operations, and any procedure in which airway protection and mechanical ventilation are required.

REGIONAL ANESTHESIA

Regional anesthesia is an attractive anesthetic option for many types of operative procedures and in select patients can provide excellent postoperative pain management. However, like any anesthetic technique, the risks and benefits associated with regional anesthesia must be assessed for each individual. Several regional techniques are in common use, including neuraxial blocks (spinal and epidural), peripheral nerve blocks, and truncal nerve blocks. Each technique has specific benefits and risks, which depend in part on the choice of local anesthetic drugs.

Local Anesthetic Drugs

Local anesthetics have played a critical role in intraoperative anesthesia since they were first described. The two classes of local anesthetic drugs in common use are amino esters and amino amides (often described as *esters* and *amides*). The mechanism of action of local anesthetics is dose-dependent blockade of sodium currents in nerve fibers. Local anesthetic drugs differ in terms of their physicochemical characteristics. Of these characteristics, the most important are pK_a, protein binding, and the degree of hydrophobicity; pK_a refers to the pH at which half the drug exists in the basic, uncharged form and half exists in the cationic form. In general, agents with a lower pK_a have a faster onset than do agents with a higher pK_a, although some agents, such as chloroprocaine, can be given at much higher concentrations, thereby offsetting the effects of a high pK_a. Because all commonly used local anesthetics have relatively high pK_a values, they are largely ineffective in acidotic (inflamed) environments in which local anesthetics exist primarily in the ionized form, as this form does not penetrate nerves. In general, greater hydrophobicity is associated with greater potency, and increased protein binding correlates with a longer duration of action. The development of liposomal bupivacaine has the potential to prolong analgesia after local administration. Liposomal bupivacaine is composed of bupivacaine encapsulated in multivesicular liposomes and can provide up to 72 hours of analgesia after local infiltration. Liposomal bupivacaine was approved by the FDA for local wound infiltration and for interscalene block. A review of the current literature by Ilfeld and colleagues demonstrates a preponderance of evidence that liposomal bupivacaine does not provide superior pain control compared with standard local anesthetics and its routine use cannot be supported.[56] The speed of onset, duration of action, and typical doses of agents commonly used for regional anesthesia or local anesthesia are summarized in Table 20.7.

An area of intense research interest has been the use of α_2-adrenergic agents to potentiate or substitute for local anesthetics. Regional anesthesia was first produced with cocaine (also a local anesthetic) for subarachnoid block in the late 1800s, although the specific receptors involved were not established until much later. The α_2-adrenergic drug clonidine was first used epidurally in 1984 after extensive characterization in animals. Despite side effects such as hypotension, bradycardia, and sedation, experience in thousands of patients has demonstrated considerable safety when used alone or with local anesthetics or opioids for epidural anesthesia and analgesia, subarachnoid block, or peripheral nerve block. In general, clonidine prolongs or intensifies the effects of local anesthetics or opioids and produces pain relief when used alone.

In using local anesthetics clinically, the priority is to prevent local anesthetic toxicity, which affects the central nervous and cardiovascular systems. The toxicity of local anesthetics when they are used for regional anesthesia depends on the site of injection and the speed of absorption. Inadvertent intravascular injection of local anesthetics produces toxicity with much smaller doses. The earliest signs of an overdose or inadvertent intravascular injection are numbness or tingling of the tongue or lips, a metallic taste, light-headedness, tinnitus, or visual disturbances. Signs of toxicity can progress to slurred speech, disorientation, and seizures. With higher doses of local anesthetics, cardiovascular collapse will ensue due to voltage-gated sodium channel blockade that interferes with normal action potential conduction.

Cardiovascular toxicity from bupivacaine may be particularly difficult to treat. One approach intended to reduce the cardiovascular toxicity of bupivacaine (a racemic mixture of the *levo* and *dextro* isomers) has been to produce a solution consisting of only the levo isomer. In healthy male volunteers, slow IV infusion of levobupivacaine reduced the mean stroke index, acceleration index, and ejection fraction less than racemic bupivacaine did. Ropivacaine, a newer potent amide local anesthetic, was compared with bupivacaine and lidocaine in volunteers receiving a slow IV infusion until CNS symptoms first occurred. Bupivacaine increased QRS width during sinus rhythm and reduced both systolic and diastolic function, whereas ropivacaine reduced only systolic function. The anesthetic properties of ropivacaine are similar to bupivacaine, and, based on its decreased toxicity profile, it is commonly used as an alternative to bupivacaine by many practitioners.

The best defenses against local anesthetic systemic toxicity (LAST) are aspiration of needles and catheters delivering medication to detect unplanned vascular entry before injecting large doses of local anesthetics and knowledge of the maximal safe dose of the drug being injected. Adding epinephrine, which slows

TABLE 20.7 **Important Characteristics of Local Anesthetics for Major Nerve Blocks**

LOCAL ANESTHETIC	AMINOAMIDE OR AMINO ESTER	SPEED OF ONSET (MIN)	DURATION OF ACTION (MIN)	MAXIMAL DOSE[a] (AXILLARY BLOCK)
Lidocaine	Amino amide	10–20	60–180	5 mg/kg
Mepivacaine	Amino amide	10–20	60–180	5 mg/kg
Bupivacaine	Amino amide	15–30	180–360	3 mg/kg
Ropivacaine	Amino amide	15–30	180–360	3 mg/kg
Chloroprocaine	Amino ester	10–20	30–50	Not generally used

[a] Maximal dose without epinephrine; doses of lidocaine and mepivacaine can be increased to 7 to 8 mg/kg if epinephrine is added. Lower doses may be toxic if infiltrated subcutaneously, as for intercostal nerve blocks; larger doses of lidocaine and mepivacaine may be tolerated if given by epidural injection.

absorption, also decreases the likelihood of a toxic response secondary to rapid absorption. The primary treatments of LAST are cessation of local anesthetic administration, airway management, seizure treatment with benzodiazepines, and cardiovascular support. Current guidelines from the American Society of Regional Anesthesia (ASRA) Pain Medicine recommend administration of a 1.5 mL/kg bolus of 20% lipid emulsion (calculated using lean body mass) over 2 to 3 minutes with a subsequent infusion of 0.25 mL/kg/min until stable (maximum dose 12 mL/kg ideal body weight). Additionally, if cardiovascular collapse occurs, several alterations to the advanced cardiac life support algorithm must be considered. Epinephrine dosing should be reduced to boluses of 1 μg/kg and all local anesthetic antiarrhythmics, β-blockers, calcium channel blockers, and vasopressin should be avoided.[57]

Spinal Anesthesia

Spinal anesthesia or subarachnoid block has many applications for urologic, lower abdominal, perineal, and lower extremity surgery. Spinal anesthesia is induced by the injection of local anesthetic, with or without opiates, into the subarachnoid space. A well-performed subarachnoid block provides excellent sensory and motor blockade below the level of the block. The block generally has a relatively rapid and predictable onset. Several factors determine the level, speed of onset, and duration of spinal blockade.

1. Local anesthetic agent. Local anesthetics have varying potencies, durations of action, and speeds of onset after subarachnoid administration. Typical doses and durations of action are shown in Table 20.8. Bupivacaine and ropivacaine have significantly longer durations of action than lidocaine or chloroprocaine. These properties are determined by the lipid solubility, protein binding, and pK_a of each agent.
2. Volume and dose of the local anesthetic. Increasing the dose will generally increase the extent of cephalad spread and duration of subarachnoid blockade. Rapidly injecting local anesthetic solutions leads to turbulent flow and unpredictable spread.
3. Patient position and local anesthetic baricity. Local anesthetic solutions can be prepared as hypobaric, isobaric, and hyperbaric solutions, as compared with cerebrospinal fluid (CSF). A solution that is hypobaric relative to CSF will ascend relative to injection site, whereas a hyperbaric solution will sink. The level of block will be determined by the baricity of the local anesthetic solution and the physical position of the patient from the time of injection until the local anesthetic firmly binds to nervous tissue. For example, administration of hyperbaric bupivacaine at the low lumbar level to a patient in the sitting position will result in intense lumbosacral blockade. The longer the patient remains in the sitting position, the less the cephalad spread of the block.
4. Vasoconstrictors. The addition of epinephrine or phenylephrine, particularly to short-acting local anesthetics, will increase the duration of action.
5. Addition of opioids. The addition of small doses of fentanyl (e.g., 20 μg) or morphine (e.g., 0.25 mg) will prolong the duration of analgesia and increase the duration of analgesia and tolerance for tourniquet pain.
6. Anatomic and physiologic factors. A higher than expected level of spinal anesthesia can result from anatomic factors that decrease the relative volume of the subarachnoid space, such as obesity, pregnancy, increased intraabdominal pressure, previous spine surgery, and abnormal spinal curvature. Elderly patients tend to be more sensitive to intrathecally injected local anesthetics.

Spinal anesthesia provides the advantage of avoiding manipulation of the airway and the potential complication of tracheal intubation, as well as the potential side effects of general anesthetics such as nausea, vomiting, and prolonged emergence or drowsiness. Spinal anesthesia also provides advantages for several types of surgery, including endoscopic urologic procedures, particularly transurethral resection of the prostate, in which an awake patient provides a valuable monitor for assessment of hyponatremia or bladder perforation. Previously, regional anesthesia for hip fracture surgery was thought to decrease postoperative delirium and confusion compared with general anesthesia. However, a recent study by Li and colleagues found no difference in rates of postoperative delirium in patients who had undergone regional anesthesia without sedation versus those who had general anesthesia.[58] Intrathecal opiate administration can provide high-quality postoperative analgesia for patients undergoing abdominal, lower extremity, urologic, and gynecologic procedures.

In most cases, spinal anesthesia is administered as a single bolus injection. Therefore, the block is of limited duration and is not suitable for prolonged procedures. The practice of continuous spinal anesthesia with the use of small-bore catheters has largely been abandoned because of neurologic complications associated with LAST. However, continuous spinal anesthesia with relatively large-bore epidural catheters can provide the advantages of incremental titration and the ability to administer additional doses in selected elderly patients. Unfortunately, in young patients this technique has a high likelihood of inducing a postdural puncture headache.

Complications of subarachnoid block include hypotension (sometimes refractory), bradycardia, postdural puncture headache, transient radicular neuropathy, backache, urinary retention, infection, epidural hematoma, and excessive cephalad spread resulting in cardiorespiratory compromise. Frank neurologic injury, although recently described with continuous techniques using small-bore catheters, is quite rare. Hypotension, which occurs

TABLE 20.8 Local Anesthetics Used for Subarachnoid Block

DRUG	USUAL CONCENTRATION (%)	TOTAL DOSE (MG)	BARICITY	GLUCOSE CONCENTRATION (%)	USUAL DURATION (MIN)
Lidocaine	1.5, 5.0	30–100	Hyperbaric	7.5	30–60
Bupivacaine	0.5	10–20	Isobaric	0	75–200
	0.75	7.5–22.5	Hyperbaric	8.25	75–200
Chloroprocaine	3	30–60	Isobaric	0	40–80
Mepivacaine	1.5	30–80	Isobaric	0	120–180
Ropivacaine	0.5–1	12–25	Isobaric	0	80–210

From Berde CB, Strichartz GR. Local anesthetics. In: Miller RD, ed. *Anesthesia*. 5th ed. Philadelphia: Churchill Livingstone; 2000:491-522.

because of sympathectomy, usually responds readily to fluids and small doses of pressors such as ephedrine and phenylephrine. Although preloading or coloading with crystalloid versus colloid to decrease severity of arterial hypotension has been a controversial topic in the past, current evidence suggests that crystalloid coloading with an adequate speed of administration (over 5–10 minutes) is equally efficacious as coloading or preloading with colloid solutions, with lower overall risk of adverse reactions.[59]

Postdural puncture headache occurs after a small proportion of subarachnoid blocks; it is a result of traction on the meninges caused by loss of CSF through a dural hole. Factors that increase its incidence include female sex, younger age, and larger needles. Epidural analgesia would appear to avoid the complication, but if the dura is inadvertently punctured, it leaves a much larger hole, as epidural needles are much larger. Compared with epidural anesthesia, spinal anesthesia has a quicker onset, is more predictably satisfactory for surgery, and is less frequently associated with backache. Transient radicular neuropathy, a painful but usually self-limited condition, may occur with use of lidocaine for spinal anesthesia.

When cardiac arrest results from excessive cephalad spread of subarachnoid block or protracted hypotension, cardiopulmonary resuscitation is notoriously difficult. Patients who suffer cardiac arrest during subarachnoid block have poor survival, possibly because the profound sympathectomy causes difficulty in generating adequate coronary perfusion pressure. Relatively large doses of epinephrine may be necessary to achieve adequate perfusion pressure during cardiopulmonary resuscitation after spinal anesthesia. Absolute contraindications to spinal anesthesia include sepsis, bacteremia, infection at the site of injection, severe hypovolemia, coagulopathy, therapeutic anticoagulation, increased ICP (there is a theoretical risk of herniation if CSF is lost caudally), and patient refusal.

Epidural Anesthesia

Epidural block can be applied in a wide variety of abdominal, thoracic, and lower extremity procedures. Induction of epidural anesthesia or analgesia results from injection of local anesthetics, with or without opiates, into the lumbar or thoracic epidural space. Generally, a catheter is inserted once the epidural space has been located with a needle. The presence of the catheter provides several advantages. First, local anesthetic can be added in a controlled fashion so that the time to onset of the block can be well controlled. Second, the catheter can be used for repeated dosing so that anesthesia can be provided for the duration of lengthy procedures. Third, local anesthetics or opiates can be administered for several days to provide postoperative analgesia.

Epidural anesthesia using low concentrations of local anesthetics in conjunction with epidural opiates has several advantages over traditional parenteral opiates for analgesia in the postoperative period. It provides superior pain control, less sedation, better pulmonary function, earlier ambulation and less postoperative ileus after abdominal surgery, and decreased duration of mechanical ventilation. Additionally, epidural anesthesia has been shown to decrease blood loss and deep venous thrombosis during total joint arthroplasty.

Thoracic epidural anesthesia, but not lumbar epidural anesthesia, appears to be associated with more rapid recovery of gastrointestinal function after major abdominal surgery. However, postoperative IV lidocaine also resulted in more rapid return of bowel function (flatus and bowel movement) and decreased postoperative pain in both open abdominal and laparoscopic procedures. Thus, circulating systemic lidocaine may account for at least some of the effects of epidural anesthesia on postoperative bowel function and may be as efficacious as epidural analgesia in some circumstances. However, effectiveness of IV lidocaine may vary by surgical procedure.[60] A continuing controversy relates to whether epidural or subarachnoid analgesia reduces subsequent analgesic requirements after the block has resolved (so-called preemptive analgesia).

The complications and contraindications associated with epidural anesthesia are similar to those for spinal anesthesia. A special cautionary note is indicated regarding neuraxial anesthesia and anticoagulation. Because of the risk of epidural hematoma that can result in cord compression, spinal anesthetics as well as placement and removal of epidural catheters in patients receiving oral or parenteral anticoagulation must follow certain guidelines governing interval between medication and intervention. The advent of low-molecular-weight heparin (LMWH) for prophylaxis of deep venous thrombosis and the advent of increasingly potent antithrombotic medications have increased the risk of epidural hematomas associated with the removal or placement of epidural catheters. Although LMWH is effective as prophylaxis against venous thromboembolism, spinal hematomas have occurred in association with perioperative use of LMWH in patients given neuraxial analgesia. The timing of catheter placement and removal in the setting of LMWH and other antithrombotic agent use is critical to avoiding this rare but catastrophic complication. Current consensus guidelines from ASRA Pain Medicine in conjunction with the European Society of Anaesthesiology and Intensive Care outline recommendations for anticoagulation administration before neuraxial insertion, during neuraxial catheter maintenance, and after procedure termination or catheter removal.[61] Timing of appropriate neuraxial placement varies greatly depending on the anticoagulation type and dose administered. Additionally, almost all anticoagulants except for unfractionated heparin are contraindicated when a neuraxial catheter is in place. Therefore, minimizing risk of epidural hematomas in the setting of neuraxial analgesia requires close consultation with anesthesia colleagues and utilization of the ASRA Pain Medicine guidelines to develop optimal anticoagulation plans for patients.

A high index of suspicion of epidural hematoma must be maintained in patients undergoing neuraxial blockade who have received or will receive anticoagulation. All persons involved in the care of patients receiving continuous epidural analgesia must be aware of the signs of epidural hematoma, including back pain, lower extremity sensory and motor dysfunction, and bladder and bowel abnormalities. Epidural abscess, a final rare complication, should be considered in patients in whom back pain develops after epidural injection; magnetic resonance imaging is an effective diagnostic tool in such patients.

Peripheral Nerve Blocks

Blockade of the brachial plexus, lumbar plexus, and specific peripheral nerves is an effective means of providing surgical anesthesia and postoperative analgesia for many surgical procedures involving the upper and lower extremities. When used as the primary anesthetic, peripheral nerve blocks can allow for avoidance of the downsides of general anesthesia, including airway manipulation, and compared with spinal or epidural anesthesia, they avoid sympathectomy and consequent physiologic derangements. This strategy requires a cooperative patient, an anesthesiologist skilled in peripheral nerve blocks, and a surgeon who is accustomed to operating on awake patients. All patients undergoing peripheral nerve block receive full preoperative evaluation under the assumption that general anesthesia could be used if the block is inadequate. Most often, blocks are used as part of a larger strategy that includes sedation or even a general anesthetic and have their benefit postoperatively.

Improvements in nerve block equipment and methodology, as well as the availability of a wide range of local anesthetics, have greatly improved the effectiveness and safety of peripheral nerve blocks. In addition to providing surgical anesthesia, peripheral nerve blocks and the placement of indwelling catheters for a prolonged nerve block provide excellent analgesia for many types of upper extremity surgery and trauma. An additional application of indwelling catheters is enhancement of blood flow after reattachment of amputated limbs and in patients with peripheral vascular disease. Each particular block has specific associated risks and benefits, but general complications include LAST, nerve injury, inadvertent neuraxial block, and intravascular injection of local anesthetics.

Abdominal Wall Blocks

The use of anterior abdominal wall blocks has increased over the past decade due to the adoption of minimally invasive and laparoscopic surgical procedures and can provide somatic pain relief in the targeted nerve distribution. Transversus abdominis plane and rectus sheath blocks are relatively easy to place under ultrasound guidance and are generally safe and effective when applied in the proper clinical context. Other abdominal wall blocks include ilioinguinal-iliohypogastric and quadratus lumborum blocks. Prospective clinical trials and meta-analyses have generally shown that abdominal wall blocks confer some analgesic benefit in adult and pediatric patients undergoing minimally invasive or laparoscopic intraabdominal procedures. Variability in results likely stems from differing approaches to performing these blocks.[62] Abdominal wall blocks also have the potential to provide analgesic benefit in patients undergoing open intraabdominal surgery who have contraindications to epidural analgesia.

Enhanced Recovery After Surgery Pathways

As patients become more complex and available treatment options expand, increasing variability has been noted in clinical management.[63] Enhanced Recovery After Surgery (ERAS) pathways have been applied to standardize perioperative management of surgical patients, with the goal of optimizing patient outcomes and improving healthcare efficiency. ERAS protocols include guidance for fluid management, pain control, temperature regulation, minimally invasive surgical approach, removal of tubes and drains, and early mobilization. They originated in the colorectal surgery space but have been applied to numerous other surgical populations.[64–66] These protocols are ideally built in a multidisciplinary fashion using an evidence-based approach that features continuous auditing, reporting, and adjustment.[67] Although these pathways do not replace clinical judgment or suggest a retreat from patient-centered care, they strive to streamline systems operations and routinely connect patients with the most up-to-date, evidence-based practices relevant to their care.

CONSCIOUS SEDATION

When anesthesiologists participate in the sedation of patients undergoing surgical procedures, the anesthetic is termed *monitored anesthesia care*, or MAC. MAC encompasses a wide range of depths of sedation ranging from anxiolysis (minimal) to deep sedation. Minimal sedation indicates that the patient has normal responses to verbal stimulation with no impairment of airway patency, ventilation, or cardiovascular function. Moderate sedation, often termed *conscious sedation* by nonanesthesiologists, indicates that the patient has purposeful responses to verbal or tactile stimulation, has a patent airway requiring no intervention, demonstrates adequate spontaneous ventilation, and has maintained cardiovascular function. There is a narrow margin between minimal sedation, which may be inadequate for surgery, and deep sedation, which may result in airway compromise as well as cardiovascular and respiratory depression. Although relatively rare in this setting, a closed claim analysis showed that hypoventilation and hypoxemia were the most common major complications of moderate sedation.[68] Because of the risks associated with moderate sedation, The Joint Commission requires that patients be managed with precautions similar to what they would receive if an anesthesiologist was managing the sedation. This includes the necessity for preprocedural evaluation, including an airway assessment, continuous presence of a trained monitoring assistant who has no other responsibilities throughout the procedure, immediate availability of airway and resuscitation equipment, monitoring after the procedure until the effects of sedation have resolved, and specific written postoperative instructions. Physicians who perform procedures under conscious sedation are granted privileges in line with their training and experience in the appropriate resuscitative procedures. Deep sedation and general anesthesia can only be administered by a licensed anesthesia provider or medical staff with privileges to administer deep sedation or general anesthesia, in accordance with hospital policy and state scope of practice laws.[69]

Drugs used for moderate sedation usually consist of an opioid such as fentanyl combined with an anxiolytic such as midazolam. Medications such as dexmedetomidine and ketamine can be useful nonopioid adjuncts. Titration of these agents requires careful assessment of a patient's level of pain or anxiety and the requirements for the surgical procedure. Induction agents such as propofol can be used for moderate sedation outside of the operating room, and while generally safe when used under proper conditions, this introduces an added element of risk due to potentially rapid progression to deep sedation or general anesthesia. Most hospitals now have specific policies and procedures governing moderate sedation. Those who use moderate sedation outside hospitals (e.g., in office-based surgical practices) need to follow the same precautions as practiced in the hospital environment.

POSTANESTHESIA CARE

The PACU is the area designated for the care of patients recovering from the immediate physiologic and pharmacologic consequences associated with anesthesia and surgery. The PACU ideally is located close to the operating rooms. Monitors for the assessment of ventilation, oxygenation, and circulation must be available for all recovering patients. Care also includes periodic assessment of neuromuscular function, mental status, temperature, pain, fluid status, urine output, nausea and vomiting, and bleeding and drainage. The extent of monitoring depends on the condition of the patient. The ASA has established standards for postanesthesia care.[70] Recovery from anesthesia is usually uneventful and routine. Most patients stay in the PACU for 30 to 60 minutes until they are fully reactive and can move to a second-stage recovery area (for ambulatory patients who are returning home that day) or to a bed on a surgical floor. However, several criteria need to be met before the patient can be safely discharged from the PACU.

Patients must be awake and oriented (if they were before anesthesia) and have stable vital signs. Patients must be breathing without difficulty, able to protect their airways, and oxygenating appropriately. Pain, shivering, nausea, and vomiting must be adequately controlled. Patients receiving neuraxial anesthesia must be observed for resolution of the block. Surgical complications such as postoperative bleeding or unacceptable drain output must be addressed before discharge from the PACU. Several types of anesthesia-related complications can be encountered in the PACU and must be promptly recognized and treated to prevent serious injury.

Postoperative Agitation, Delirium, and Cognitive Decline

Pain and anxiety often manifest as postoperative agitation, but agitation may also signal serious physiologic disturbances such as hypoxemia, hypercapnia, acidosis, hypotension, hypoglycemia, surgical complications, overdistended bladder, or adverse drug reactions. Serious underlying conditions must be excluded as the cause of agitation before empirically treating patients with pain medications, sedatives, or physical restraints.

Postoperative delirium is a common complication of surgery and anesthesia that occurs in 5% to 10% of low-risk patients and up to 40% of high-risk patients, such as those older than 60 undergoing major procedures like cardiac surgery.[71] Development of postoperative delirium in the elderly is associated with increased mortality, persistent cognitive decline, and prolongation of in-hospital care. Factors contributing to postoperative delirium are multifactorial and include preoperative cognitive function, extent of surgery, and the need for postoperative intensive care. Approaches to minimizing postoperative delirium are under investigation and include avoidance of perioperative benzodiazepines and careful titration of anesthetic depth.[71] In a recent study, there was no benefit to using regional anesthesia without sedation over general anesthesia on rates of postoperative delirium in hip fractures.[58]

Respiratory Complications

Respiratory complications occur frequently in the PACU. Airway obstruction is most commonly due to obstruction of the oropharynx by the tongue or oropharyngeal soft tissues as a result of the residual effects of general anesthetics, pain medications, or muscle relaxants, often in combination with existing OSA. Other causes of airway obstruction include laryngospasm; blood, vomitus, or debris in the airway; glottic edema; vocal cord paralysis; and external compression of the airway by a hematoma, dressing, or cervical collar. Oxygen must be administered to a patient with airway obstruction as measures are taken to relieve the obstruction. The characteristic physical signs of airway obstruction are sonorous respiratory sounds and paradoxical chest/abdomen movement.

Many obstructions created by the tongue and soft tissue can be relieved by simply applying a head-tilt and jaw-thrust maneuver with or without placement of an oral or nasopharyngeal airway. Use of quantitative neuromuscular monitoring devices intraoperatively reduce in the incidence of postoperative respiratory complications such as obstruction and hypoxia caused by residual neuromuscular blockade.[19] In cases of laryngospasm, continuous positive airway pressure is applied. If this is not successful in breaking the spasm, low doses of propofol—or in severe cases, succinylcholine—can be administered. If the laryngospasm does not resolve promptly, a patient may require mask ventilation and endotracheal intubation. In children, glottic edema or postextubation croup can result in airway obstruction. Mild cases are treated with humidified oxygen. Refractory obstruction may require the administration of systemic steroids and nebulized racemic epinephrine. Reintubation may be required.

Hypoxemia is a surprisingly common problem, and administration of supplemental oxygen during transportation to the PACU and during the immediate postoperative period decreases the incidence and severity of hypoxemia. Hypoxemia can result from inadequate alveolar recruitment, hypoventilation, ventilation-perfusion mismatching, or right-to-left intrapulmonary shunting. Reluctance to inspire deeply after abdominal or thoracic surgery may also result in hypoxemia. Clinically, hypoxemia must be suspected as an underlying problem in patients exhibiting restlessness, tachycardia, or cardiac irritability. Bradycardia, hypotension, and cardiac arrest are late signs. Hypoxemia in the PACU is frequently secondary to atelectasis, which may respond to incentive spirometry and encouragement to cough. Treatment of hypoxemia requires the administration of oxygen, assurance of adequate ventilation, and treatment of the underlying causes. Patients with sleep apnea may benefit from use of positive pressure support.

Hypoventilation resulting in hypercapnia can result from airway obstruction; central respiratory depression caused by anesthetic agents and/or opioids, hypothermia, CNS injury; or restriction of ventilation secondary to muscle relaxants, abdominal distension, and electrolyte abnormalities. Signs can include prolonged somnolence, a slow (or rapid but shallow) respiratory rate, airway obstruction, tachycardia, and arrhythmias. Severe hypoventilation can result in hypoxemia, although augmented inspired oxygen will limit the severity of hypoventilation-induced hypoxemia. Treatment is aimed at identification and treatment of the underlying problem. Naloxone can be used to rapidly reverse hypoventilation caused by opioids. In all cases, ventilation must be supported until corrective measures are instituted. Obtundation, circulatory depression, and severe respiratory acidosis are indications for endotracheal intubation and ventilatory support.

Postoperative Nausea and Vomiting

One of the most common problems in the PACU is PONV. Risk factors include female sex, postoperative opioid administration, nonsmoking status, a history of PONV or motion sickness, young patient age, longer duration of anesthesia, exposure to volatile anesthetics, and the type of surgery. A Cochrane review found aprepitant, ramosetron, granisetron, dexamethasone, and ondansetron reduce postoperative vomiting, with NK_1 receptor antagonists such as aprepitant being the most effective.[72] Fosaprepitant and droperidol probably reduce vomiting compared with placebo but were less effective than the other drugs. A combination of medications to prevent PONV is more efficacious than a single medication (Table 20.9). Due to its ability to prolong the QTc interval, droperidol was given a black box warning by the FDA, recommending ECG monitoring before and after administration of the drug.

The mechanisms that cause nausea and vomiting should guide the approach to PONV prophylaxis and treatment. Areas in the brainstem that control nausea and vomiting reflexes, such as the chemoreceptor trigger zone, contain receptors for dopamine, acetylcholine, histamine, and serotonin. Activating these receptors may precipitate nausea, vomiting, or both. Effective pharmacologic approaches to the treatment of PONV include the use of $5\text{-}HT_3$ receptor antagonists, D_2 receptor antagonists, NK_1 receptor antagonists, corticosteroids, and antihistamines. The use of any particular agent is based on efficacy, potential side effects, and cost. In patients at high risk of PONV or in those with a history of PONV, it is often effective to employ a multimodal approach, including the avoidance of volatile anesthetics.

TABLE 20.9 Commonly Used Antiemetic Agents

DRUG CLASS	COMMON SIDE EFFECTS
Dopamine Receptor Antagonists (D_2)	
Phenothiazines	
Chlorpromazine	Sedation
Prochlorperazine	
Butyrophenones	Dissociation
Haloperidol	
Droperidol	Extrapyramidal effects
Metoclopramide	
Antihistamines (H_1)	
Diphenhydramine	Sedation
Promethazine	Dry mouth
Anticholinergics	
Scopolamine	Sedation
Atropine	Dry mouth, tachycardia
Serotonin Receptor Antagonists	
Ondansetron	Headache, constipation
Aprepitant	
Corticosteroids	
Dexamethasone	Glucose intolerance
Methylprednisolone	Altered wound healing
Hydrocortisone	Immunosuppression, renal effects

Hypothermia

Hypothermia has been extensively studied as a perioperative complication. Hypothermia can increase oxygen consumption postoperatively due to shivering, alter drug metabolism, affect blood coagulation, and increase the rate of surgical infections. Increased oxygen consumption can be a particular problem in patients with coronary artery disease in whom shivering can trigger myocardial ischemia. Risks associated with mild hypothermia have not been well defined in otherwise healthy patients. Nevertheless, the Centers for Medicare and Medicaid Services has designated perioperative normothermia as a quality indicator and Pay for Performance issue. Hospitals and medical centers receive financial incentives if they report on and achieve perioperative normothermia (a measured temperature of 35.5°C [95.9°F] within the 30 minutes immediately before or the 15 minutes immediately after anesthesia end time for procedures lasting for more than 1 hour).

General anesthesia has profound effects on thermoregulatory mechanisms, and active intraoperative warming is required to maintain normothermia (core temperature >36°C) under most conditions. Anesthetic-induced vasodilation redistributes blood from the core to the periphery, where heat is rapidly lost via radiation to the surrounding environment. Heat is also lost via conduction, convection, and evaporation. Forced air and circulating water warmers are the most effective techniques for providing active intraoperative warming, each having advantages under different conditions. IV fluid warmers and airway warming devices can also be useful for minimizing heat loss but do not allow for active warming. Preoperative warming can minimize core hypothermia in patients undergoing procedures lasting less than an hour. Prophylactic warming decreases the incidence of postoperative hypothermia and need for intervention in the outpatient surgical setting, though time to PACU discharge and patient satisfaction are not affected. The use of prophylactic warming is associated with a significant increase in cost. Therefore, guidelines for temperature management during short, outpatient surgical procedures remain to be fully implemented.

Circulatory Complications

Hypotension in the PACU is most commonly due to hypovolemia. Other causes include residual anesthetic effect, cardiac dysfunction, arrhythmias, anaphylaxis, transfusion reactions, cardiac tamponade, pulmonary emboli, adverse drug reactions, adrenal insufficiency, and hypoxemia. Treatment involves supporting the circulation with fluids, vasoactive medications, the Trendelenburg position, and delivery of oxygen until the underlying cause is diagnosed and treated.

Hypertension is also a common finding in the PACU. Common causes include pain, anxiety, and inadequately managed essential hypertension. Hypercapnia should be ruled out. Other less common causes include hypoglycemia, drug reactions, diseases such as hyperthyroidism, pheochromocytoma, or MH, and bladder distention. The fundamental goal in control of postoperative hypertension is to identify and correct the underlying cause.

Postoperative Visual Loss

Postoperative visual loss is a rare but devastating complication that occurs most commonly in patients undergoing prolonged surgery in the prone position (spine surgery) or cardiac surgery. The overall incidence is reported as 0.03% to 0.2%. Causes include central retinal artery occlusion, cortical blindness, and ischemic optic neuropathy. Risk factors for the development of postoperative visual loss are not completely understood but include obesity, prolonged length of surgery, high intraoperative blood loss, and lower colloid to crystalloid ratio during resuscitation.[73] Because of the seriousness of the complication, the ASA has released practice advisory on postoperative visual loss.[74]

ACUTE PAIN MANAGEMENT

Pain, one of the most common and significant symptoms experienced by surgical patients, has historically been poorly evaluated and frequently undertreated. There have been massive shifts in medical care with respect to pain management, starting with a clarion call in 1990 for improved focus on pain assessment and treatment, to the declaration of pain as the fifth vital sign by The Joint Commission in 2001, through the opioid epidemic that has ensued. With increased focus on pain management, institutions have established protocols and procedures for pain management, the subspecialty of pain medicine was developed, and there has been increased interest from governmental and third-party payers. Medical personnel must continue to increase their knowledge of pain control options and their commitment to provide optimal analgesia as a key component of patient care, while avoiding the overprescribing practices that sparked a national opioid epidemic. Surveys demonstrate that continued improvement is necessary to reduce the high incidence of moderate to severe acute postoperative pain.

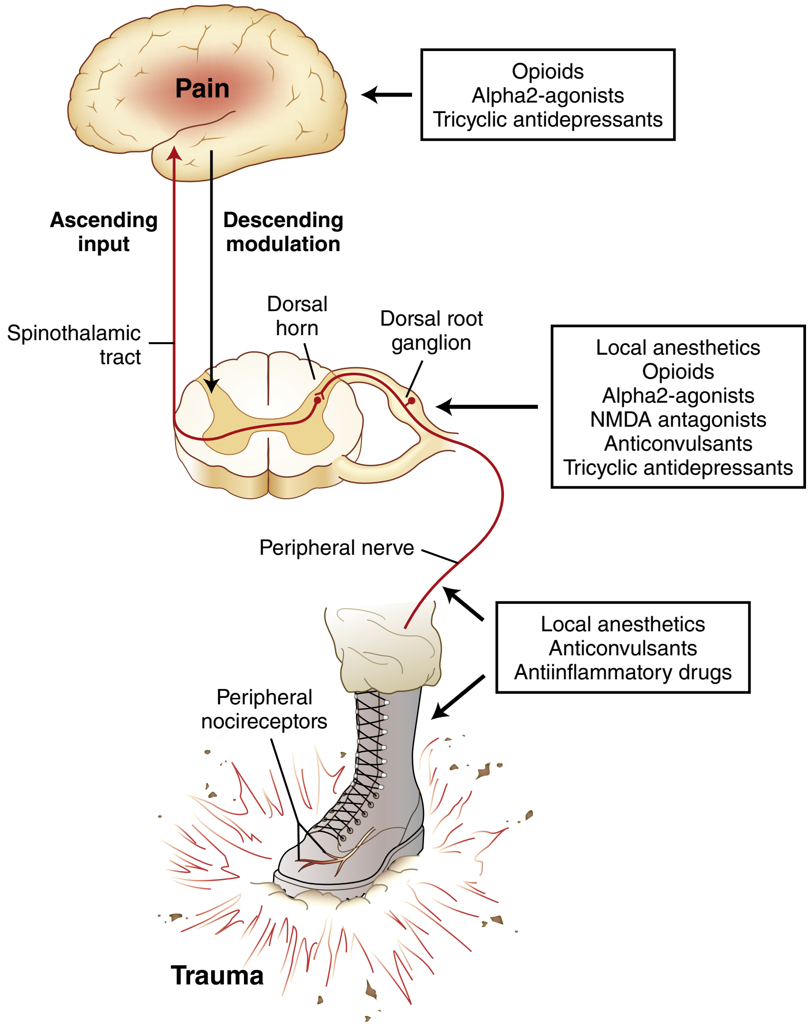
Acute pain occurs frequently in the setting of surgery and trauma. The pain experience may be part of the symptom complex that prompts the patient to seek medical care, or it may be caused by tissue injury sustained as a result of surgery or trauma. The term *acute pain* refers to pain that is expected to be of relatively short duration and that should resolve with tissue healing or withdrawal of the noxious stimulus. Acute pain generally resolves within minutes, hours, or days. *Chronic pain*, or persistent surgical pain, is defined as pain that persists for at least 3 months beyond the usual course of an acute disease or beyond a reasonable time in which an injury would be expected to heal.[75] The acute stress response associated with acute pain serves a useful function, although undertreatment may result in harmful pathophysiologic changes. Chronic pain serves no useful function and is now recognized as a disease itself.

Mechanisms of Acute Pain

The International Association for the Study of Pain defines pain as "an unpleasant sensory and emotional experience associated with, or resembling that associated with, actual or potential tissue damage." This definition emphasizes not only the sensory experience but also the affective component of pain. The tissue injury results in a process called nociception, which has four steps: transduction, transmission, modulation, and perception. With transduction, the noxious stimulus is converted into an electrical signal at free nerve endings, which are also known as nociceptors. Nociceptors are widely distributed throughout the body in both somatic and visceral tissues. With transmission, the electrical signal is sent via nerve pathways toward the CNS. Nerve pathways include primary sensory afferents (primarily Aδ and C fibers) that project to the spinal cord, ascending tracts (including the spinothalamic tract) that project to the brainstem and thalamus, and thalamocortical pathways that project to the cortex. Modulation, the process that either enhances or suppresses the pain signal, occurs primarily in the dorsal horn of the spinal cord, specifically the substantia gelatinosa. Perception, the final step in the nociceptive process, occurs when the pain signal reaches the cerebral cortex. Multiple things can affect the perception of pain, making the experience extremely subjective and widely variable. The first three steps in nociception are important for the sensory and discriminative aspects of pain. The fourth step, perception, is integral to the subjective and emotional experience.

Methods of Analgesia

Multiple agents, routes of administration, and modalities are available for effective management of acute pain (Fig. 20.4). Analgesic agents can be chosen based on the type of pain



Pain
Opioids
Alpha2-agonists
Tricyclic antidepressants
Ascending input
Descending modulation
Spinothalamic tract
Dorsal horn
Dorsal root ganglion
Local anesthetics
Opioids
Alpha2-agonists
NMDA antagonists
Anticonvulsants
Tricyclic antidepressants
Peripheral nerve
Local anesthetics
Anticonvulsants
Antiinflammatory drugs
Peripheral nocireceptors
Trauma

FIGURE 20.4 Schematic diagram outlining the nociceptive pathway for transmission of painful stimuli. Interventions that prevent nociceptive transmission are shown at the points in the pathway that are thought to be their sites of action. *NMDA, N*-methyl-D-aspartate. (From Buckenmaier CC III, Bleckner LL, eds. *Military Advanced Regional Anesthesia and Analgesia*. Washington, DC: Borden Institute, Walter Reed Army Medical Center; 2008.)

(somatic versus neuropathic) and include opioids, nonsteroidal anti-inflammatory drugs (NSAIDs), acetaminophen, gabapentinoids, muscle relaxants, NMDA receptor antagonists, α_2-agonists, and local anesthetics. Opioid agonist/antagonists such as buprenorphine are now routinely used for treatment of pain as well as for opioid use disorder. Routes of administration include oral, parenteral, epidural, and intrathecal routes. Patients experiencing mild to moderate acute pain can obtain effective analgesia with oral analgesics. Parenteral administration is preferred for patients experiencing moderate to severe pain, patients who require rapid control of pain, and those who cannot receive agents through the gastrointestinal tract. The IV route is preferred over IM and subcutaneous injections when the parenteral route is indicated. IM injections are painful, result in erratic absorption, and lead to variable blood levels of the administered agent.

Opioids

Opioids are potent analgesic agents that have been used for centuries but come with potentially harmful side effects. By binding to opioid receptors in the CNS, opioids modulate the nociceptive process. The best-characterized opioid receptors are μ_1, μ_2, δ, and κ receptors. The μ_1 receptors are involved in supraspinal analgesia. The δ and κ receptors are involved in spinal analgesia. Opioids can be administered via oral, parenteral, neuraxial, rectal, and transdermal routes.

Opioids have varying degrees of potency. Strong opioids are ideal for moderate to severe pain and for pain that is constant in frequency. Weak opioid agents are suitable for mild to moderate pain that is intermittent in frequency. Morphine is the prototypical strong opioid. It is broken down into to the active metabolites morphine-3-glucoronide and morphine-6-glucoronide, which can accumulate in patients who have renal impairment and cause significant respiratory depression. Other commonly used strong opioids include hydromorphone, fentanyl, methadone, and meperidine. For moderate to severe pain in patients with renal dysfunction, fentanyl and hydromorphone are more suitable agents. Meperidine is an opioid that also has anticholinergic, local anesthetic, serotonergic, and noradrenergic properties. Its use has declined because meperidine is metabolized to normeperidine, a unique toxic metabolite that can accumulate and cause seizure-like activity. Patients who are particularly vulnerable to this side effect include the elderly, patients who are dehydrated, and those with renal impairment. Methadone is a long-acting opioid with NMDA antagonist properties, making it useful for major surgery in opioid tolerant patients.

Weak opioid agents, such as oxycodone, hydrocodone, and codeine, are commonly used in conjunction with acetaminophen for a multimodal pain regimen postoperatively. Tramadol is a weak opioid analgesic that weakly inhibits serotonin/norepinephrine reuptake. It is a centrally acting agent that is administered orally and can be used for mild to moderate pain. Common opioid-related side effects include nausea, pruritus, sedation, mental clouding, decreased gastric motility, urinary retention, and respiratory depression. Appropriate selection of agents, along with the use of a multimodal regimen and appropriate monitoring, can prevent or ameliorate these side effects.

When using opioids, it is important to recognize their importance in analgesic regimens, but also their significant side effects, including the possibility of tolerance, opioid-induced hyperalgesia, and in severe cases, the development of opioid use disorder, the diagnostic criteria of which are defined in The *Diagnostic and Statistical Manual of Mental Disorders,* 5th Edition. Key terms to understand include *tolerance, addiction* (psychological dependence), and *physical dependence.* Tolerance occurs when a previously effective opioid dose fails to provide adequate analgesia. It is a normal physiologic effect. Tolerance develops to the analgesic effect of opioids but not to most opioid-related side effects, including respiratory depression and constipation. The duration of opioid exposure also plays a role in the development of tolerance. In patients manifesting tolerance, an increased dose is required to achieve effective analgesia. Opioid-induced hyperalgesia, usually seen with prolonged exposure or high doses of opioids, can reduce the baseline pain threshold, thereby making it seem as if the patient requires higher than average doses of opioids for the same analgesic effect. Addiction or psychological dependence is a compulsive disorder manifested by preoccupation with obtaining and inappropriate use of a substance, and continued use despite harm and decreased quality of life. Psychological dependence should not be confused with physical dependence, which is a normal physiologic process. Physical dependence is manifested by the occurrence of a withdrawal syndrome when use of a drug is stopped suddenly or when an antagonist is given. The duration of opioid treatment is a factor in the development of physical dependence. The short-term use of opioids in the perioperative period rarely results in physical dependence. Short courses of opioids generally preclude withdrawal symptoms.

Nonsteroidal Anti-inflammatory Drugs

NSAIDs can reduce pain and can decrease opioid consumption when used as part of a multimodal analgesic approach. Their mechanism of action is achieved through inhibition of cyclooxygenase (COX) enzyme activity, which results in decreased production of prostaglandins. Prostaglandins are potent mediators of pain that act directly at nociceptors and increase nociceptor sensitivity. Inhibition of prostaglandin production results in analgesia but can also lead to side effects such as gastric ulceration, bleeding, and renal injury. These side effects have limited the use of NSAIDs in the perioperative period.

There is a wide range of compounds in this analgesic class, with differing chemical structures. Most of these agents are orally administered, but ketorolac is available for parenteral administration. Ketorolac, like all NSAIDs, is avoided in patients with a history of gastropathy, platelet dysfunction, or thrombocytopenia; in those with a history of allergy to the agent; and in patients with renal impairment or hypovolemia. It should be used with caution in elderly patients. An optional loading dose of 30 mg IV followed by 15 mg IV every 6 hours for a short course (5 days maximum) can provide effective analgesia for mild to moderate pain or can be a useful adjunct for moderate to severe pain when combined with opioids or other analgesic techniques.

There are at least two subtypes of the COX enzyme: COX-1 (constitutive) and COX-2 (inducible). Traditional NSAIDs are nonselective inhibitors of COX. COX-2 selective medications showed promise by targeting pain with reduced risk of gastrointestinal bleeding, bleeding diathesis, and renal compromise. Celecoxib is the only COX-2 inhibitor available in the United States. This subclass of NSAIDs have mostly been studied and used clinically in the management of arthritis-related pain. In a study by Huang and colleagues,[76] the COX-2 selective inhibitor celecoxib was administered to patients undergoing total knee arthroplasty under subarachnoid blockade. Celecoxib 200 mg was administered 1 hour before surgery and every 12 hours thereafter for 5 days. Morphine use by patient-controlled analgesia (PCA) was lower in the celecoxib group (15.1 mg) versus placebo (19.7 mg). Celecoxib use was associated with a lower pain score during the first postoperative 48 hours as well as increased knee range of motion during the first three postoperative days. Morphine-related adverse effects (nausea and vomiting) did not differ between groups in this study. Concerns about the use of these selective NSAIDs include the risk for cardiovascular events and their effects on bone healing. The FDA has placed a black box warning on all NSAIDs after the COX-2 inhibitor rofecoxib was associated with increased risk of myocardial infarction and stroke.

NMDA Antagonists

NMDA antagonists may play a role in preventing central sensitization of the CNS, a proposed pathway in the development of chronic pain. Accordingly, this class of agent has reemerged in popularity for the treatment of acute perioperative pain. Ketamine has long been recognized as a powerful induction agent with strong analgesic properties, albeit at the expense of psychotropic adverse effects, including dysphoria and even psychosis at higher doses of the drug. A Cochrane review[77] of perioperative ketamine found that in a variety of surgeries, bolus dosing and/or infusion of 2 to 5 μg/kg/min reduced pain scores and improved morphine consumption at 24 and 48 hours. Results were consistent in different operation types and varied timing of ketamine administration, with larger and smaller studies, and by higher and lower pain intensity. CNS adverse events were similar with ketamine or control.[77] Ketamine reduced the area of postoperative hyperalgesia by 7 cm² (95% CI −11.9 to −2.2; negative values indicating reduction in area), but this was low-quality evidence. A study by Remérand and colleagues[78] demonstrated that perioperative ketamine was associated with 6-month reduction in chronic pain, with chronic pain incidence of 8% in the ketamine group compared with 21% in the placebo. As previously discussed, ketamine can cause hypertension and tachycardia when used in higher bolus doses, due to its sympathomimetic effects, and it does not cause significant respiratory depression. Memantine is an oral NMDA antagonist that has been used in the pain context as well[79]; the data for it are not clear, though research is ongoing.[80] Magnesium also antagonizes the NMDA receptor and has been shown to decrease postoperative pain scores in multiple surgical settings without a significant increase in adverse events,[81,82] but research remains ongoing to elucidate its long-term analgesic effects.[83]

α_2-Adrenergic Agonists

There is a high density of α_2-adrenergic receptors in the substantia gelatinosa of the dorsal horn of the spinal cord, where it is believed that α_2-adrenergic agonists impair the transmission of pain signals. Clonidine, due to its potent antihypertensive properties, is of limited use in the perioperative setting. Dexmedetomidine, an α_2-adrenergic agonist mainly used as a sedative in the ICU, is becoming more popular in the perioperative context. When administered for acute pain after abdominal surgery in adults, dexmedetomidine seems to have some opioid-sparing effect but no important differences in postoperative pain when compared with placebo.[84] A randomized controlled trial of opioid-free anesthesia using dexmedetomidine (versus remifentanil) was stopped early due to several episodes of clinically significant bradycardia in the dexmedetomidine group. They found no differences in pain postoperatively, but there was a reduction in morphine consumption and PONV at 48 hours.[85] Aside from analgesic benefits, dexmedetomidine seems to have other perioperative advantages. Ji and colleagues[86] evaluated the long-term effects of dexmedetomidine in cardiac surgery patients. This study began an infusion upon weaning from cardiopulmonary bypass and continued it into the ICU for less than 24 hours. They noted a reduction in in-hospital, 30-day, and 1-year mortality and a reduction in overall complications, including delirium. Pain scores were not described by the authors. Guanfacine is an orally administered α_2-adrenergic agonist gaining attention for delirium treatment and as a pain management adjunct, though further study is needed to assess its efficacy in the perioperative setting. It has minimal cardiovascular side effects.

Gabapentinoids

Gabapentin and pregabalin are used for the treatment of chronic neuropathic pain, and there has been significant attention to including them in perioperative multimodal analgesic regimens. Current guidelines from the American Pain Society and European Society of Regional Anesthesia and Pain Therapy offer conflicting recommendations for the use of gabapentinoids in the perioperative period. Although there have been studies suggesting an analgesic benefit, the doses of gabapentin needed to realize those benefits were 900 or 1200 mg. For example, a study by Khan et al.[87] found decreased morphine use in the first 24 hours after lumbar laminectomy as well as lower pain scores and side effects when 900 or 1200 mg of gabapentin was administered either preoperatively or postoperatively. However, recent analyses have raised doubts about the benefit of these drugs as well as concerns about the potential harm they may cause. A meta-analysis of 281 trials found no clinically significant analgesic effect of perioperative gabapentinoids, and while PONV occurred at a slightly lower rate, dizziness and visual disturbance were more common in the gabapentinoid group.[88] A cohort study of 967,547 patients over 65 years of age demonstrated an increased risk of delirium, new antipsychotic use, and pneumonia with use of gabapentin after major surgery.[89]

Local Anesthetics for the Management of Acute Pain

Local anesthetics work by blocking sodium channels, thus inhibiting conduction in nerve fibers, and can be used as IV adjuncts for blockade of nerves as part of regional anesthetics, and as neuraxial agents. Several of these indications are described at length in other portions of the chapter. Continuous infusions of lidocaine may improve pain scores, but data are mixed due to variable study design and quality.[90] There is mixed evidence for use of local anesthetic infiltration at incision sites, with some studies suggesting no change in postoperative pain scores or opioid use[91,92] and others demonstrating improvement in pain with infiltration.[93] Topical local anesthetics—such as eutectic mixture of local anesthetics (EMLA) cream (containing prilocaine and lidocaine)—can be used for superficial procedures, but they must be applied significantly in advance.

Multimodal Analgesic Therapy

Combining agents from multiple analgesic classes can have synergistic effects, potentiating benefits and reducing required doses of each agent, therefore decreasing side-effect burdens. Common combinations include opioids, NSAIDs, acetaminophen, gabapentinoids, and local anesthetics in an analgesic regimen. The choice of agent and technique depends on factors such as the patient's medical history, the patient's preference, the extent of surgery, the expected degree of postoperative pain, the experience of the staff providing care for the patient, and the postoperative setting in which the patient will recover.

Neuraxial Analgesia

Neuraxial routes of administration include the epidural and intrathecal (subarachnoid) routes. These modes of administration require consultation from acute pain specialists, usually anesthesiologists who receive specialized training in use of the neuraxial route for the administration of anesthesia and analgesia. Neuraxial agents are delivered by a single injection into the epidural or subarachnoid space, by intermittent injections through an indwelling epidural catheter, by continuous infusion through an indwelling epidural catheter, or by patient-controlled epidural analgesia through an indwelling catheter. Indwelling subarachnoid catheters are rarely used for acute pain. An important consideration in selecting patients for neuraxial analgesia is the presence of abnormal coagulation, including concurrent use of antiplatelet and anticoagulant agents. Knowledge of such coagulation issues is important to minimize the risk for intraspinal bleeding and spinal hematoma formation, which can lead to severe neurologic injury. The neuraxial route requires education of the medical and nursing staff and the use of protocols and guidelines. In general, patients can be managed on surgical floors with these analgesic techniques. However, monitoring standards need to be in place to minimize the development of common side effects, such as hypotension.

Common agents used neuraxially include opioids and local anesthetics. Opioids, when delivered by the neuraxial route, act at opioid receptors in the dorsal horn of the spinal cord and can be given in much smaller doses than when administered systemically. A drug's lipid solubility has significant impact on pharmacokinetics and dynamics when it is administered epidurally. A hydrophilic opioid, when delivered into the epidural or subarachnoid space, remains in the CSF longer than a lipophilic opioid. Such a drug can travel rostrally to the brain and influence the respiratory centers hours after initial delivery. Morphine is hydrophilic, which accounts for its slow onset of analgesia, long duration of action, ability to provide analgesia over a wide dermatomal distribution, and the risk for late respiratory depression. Fentanyl is lipophilic, which accounts for its fast onset and short duration of action, ability to provide segmental analgesia, and limited risk for late respiratory depression.

Local anesthetics, when used for neuraxial analgesia, provide analgesia by blocking nerve conduction. To achieve neuraxial analgesia, local anesthetics are delivered in smaller doses and weaker concentrations than those required to achieve surgical anesthesia. This resulting sensory blockade is sufficient to provide analgesia but not sufficiently profound to interfere with motor function and mask complications. Analgesic concentrations of local anesthetics also cause less impairment of sympathetic tone. Bupivacaine and ropivacaine are the most commonly used local anesthetics for epidural analgesia. They affect sensory fibers more than motor fibers (known as *differential blockade*) and have a lower incidence of tachyphylaxis (tolerance to local anesthetic action).

Neuraxial analgesia for acute pain commonly combines opioids and local anesthetics, thus reaping the benefits of both while limiting required doses and thus side effects. A meta-analysis of the efficacy of postoperative epidural analgesia concluded that epidural analgesia, regardless of agent, location of catheter placement, and type of pain assessment provided analgesia superior to that of parenteral opioids.[94]

Intravenous Patient-Controlled Analgesia

IV PCA minimizes the steps in the delivery of analgesia and increases patient autonomy and control. Opioids are the agent of choice for IV PCA. In comparing IV PCA with conventional intermittent nurse-administered opioid delivery, patients obtain prompt analgesia, receive smaller doses of opioids at more frequent intervals, can maintain blood concentration of drug in the analgesic range, and have a lower incidence of drug-related side effects. Candidates for IV PCA are patients who can understand the basic steps involved in use of the device who are willing to assume control of their analgesia, and who are physically capable of activating the device. Such patients include children as young as 4 years of age and most adults, including geriatric patients.

The preferred agents for IV PCA are opioids, with hydromorphone being the most frequently chosen and with morphine and fentanyl as common options. Orders for IV PCA must specify the drug, drug concentration, loading dose, bolus dose, continuous infusion rate (basal rate), lockout interval, and dose limits. Selection of these parameters is based on the patient's age, medical status, and level of pain. The routine use of a continuous basal infusion rate with IV PCA is not recommended because it is associated with increased risk of respiratory depression without improved pain control. It is safest to restrict the use of basal infusions to patients in special categories, including those with severe pain from extensive surgery or trauma and patients who are tolerant because of chronic opioid use.

The use of structured protocols and guidelines is encouraged for facilities using IV PCA. The medical and nursing staff need to receive training in the care of patients using this modality. There is an increased risk for complications if staff members are not trained to understand the concept of IV PCA; to perform appropriate patient selection, education, and assessment; to use appropriate drug and dose selection; and to establish appropriate monitoring requirements and protocols for management of side effects.

SPECIFIC TYPES OF ACUTE PAIN PATIENTS

Patients With a History of Chronic Pain

Pain that persists for 3 months beyond the expected time for recovery or initial onset is considered evidence of a chronic pain syndrome. Chronic pain can be somatic or neuropathic. Neuropathic pain syndromes occur when there has been injury to the nervous system (central, peripheral, or both). Central sensitization—an increase in nociceptive signaling in the CNS leading to hypersensitivity—is believed to underlie the development of neuropathic pain. Factors that may increase the risk for chronic pain include infection at the surgical site, intraoperative trauma to nerves, diabetes mellitus, and nerve entrapment by cancer.

Because chronic pain syndromes can be difficult to diagnose in the early postoperative period, it is important for physicians to perform appropriate pain assessment during postoperative follow-up. For instance, after amputation, patients might consider it strange to continue to feel sensation and pain in the location of an amputated limb and might be reluctant to volunteer information. In such circumstances, appropriate questioning may elicit the complaint and result in patient reassurance and appropriate treatment. Referral to a pain medicine consultant is appropriate when the diagnosis of a chronic postoperative pain syndrome is made. Treatment modalities include the use of adjuvant medications such as antidepressants and anticonvulsants, nerve blocks, physical therapy, and psychological techniques.

Patients who have a history of chronic pain may experience acute pain as a result of surgery or trauma differently from patients without such history. Their pharmacologic management may impact medication choices perioperatively as well. If on chronic opioid therapy, these patients may manifest tolerance as well as hyperalgesia, resulting in higher reported pain scores and doses of analgesics. Steps to achieving effective analgesia include obtaining a pain history preoperatively, choosing anesthetic and surgical techniques to minimize tissue trauma and the response to trauma, and appropriate planning for postoperative analgesia.

Patients on Buprenorphine

Patients can take buprenorphine, the opioid agonist/antagonist, for treatment of pain or for opioid use disorder. It is recommended to continue this medication[95] at a reduced dose throughout the perioperative period, but patients will then require usually larger doses of opioids to overcome the antagonist effect.[96] The most effective opioids in this setting are hydromorphone and fentanyl. Standard PO medications such as oxycodone and hydrocodone will not be effective. Administering buprenorphine acutely to a patient who requires opioids can trigger withdrawal.

Patients With a History of Substance Use Disorder

Patients with a history of substance abuse are frequently undertreated for acute pain. The following factors contribute to undertreatment in this patient population: stigma associated with drug use, misunderstanding on the part of healthcare providers, and inappropriate pain behavior (e.g., exaggerated expression of pain that is out of proportion to what a provider may expect). Effective analgesia can be obtained with strict guidelines, patient education, and appropriate use of consultants and modalities such as regional analgesia.

Pediatric Patients

Pediatric patients experience similar severity of acute postoperative and posttraumatic pain as adults. A major historical myth that has been refuted is the belief that neonates, infants, and children do not perceive pain like adults. Effective analgesia for a pediatric patient can be achieved with pain assessment tools that are tailored for this population and the use of modalities and agents similar to those used for adults. Dosage selection in a pediatric patient must be guided by patient weight. With neonates, nurse-controlled analgesia is standard. Older children can effectively use IV PCA. Regional anesthesia is increasingly being used for pediatric surgery. Epidural analgesia or that provided via a caudally placed catheter (or single shot injection) can provide effective analgesia. Placement of a peripheral catheter for infusion of local anesthetics can also be used. Topical anesthesia with local anesthetics such as the application of EMLA cream can likewise minimize pain from IV catheter placement and other superficial procedures.

Elderly Patients

As the general population ages, a growing percentage of geriatric patients are undergoing surgery or being treated for trauma. These patients will require pain assessment and evaluation tailored to their mental status and cognitive abilities. The modalities and agents used to manage acute pain in this population must take into consideration underlying disease states, side effects of common analgesics that are not recommended for the elderly, and decreased organ function.

CONCLUSIONS

Modern anesthesia is safe and effective for the vast majority of patients, in large part because of important advances in anesthesia equipment, monitors, and drugs. With a wide variety of specific techniques to choose from, selection of anesthetic and postoperative pain regimens for each patient can be based on the requirements of the surgical procedure, the patient's preferences, and the experience and expertise of the anesthesiologist. Over time, patients with more significant comorbidities are receiving surgical care. Anesthesia practice is evolving to provide adequate risk assessment and risk adjustment and to optimize the care of the surgical patient.

Avidan MS, Jacobsohn E, Glick D, et al. Prevention of intraoperative awareness in a high-risk surgical population. *N Engl J Med.* 2011;365:591-600.

Intraoperative awareness prevention is possible using processed electroencephalogram, but it is not superior to following known dosing guidelines for volatile anesthetics in healthy patients.

Fleisher LA, Fleischmann KE, Auerbach AD, et al. 2014 ACC/AHA guideline on perioperative cardiovascular evaluation and management of patients undergoing noncardiac surgery: a report of the American College of Cardiology/American Heart Association task force on practice guidelines. *J Am Coll Cardiol.* 2014;64:e77-e137.

In this extensive review, a joint task force of the American College of Cardiology and the American Heart Association reports guidelines for evaluation of patients with cardiovascular disease who are scheduled for noncardiac surgery. They thoroughly examine the importance of the history, physical findings, functional status, and the influence of various types of surgery as well as current recommendations on the perioperative use of β-blockers, statins, and other medications. The value of preoperative testing is also evaluated. This is a valuable update of a consensus approach to this topic.

Gan TJ, Belani KG, Bergese S, et al. Fourth consensus guidelines for the management of postoperative nausea and vomiting. *Anesth Analg.* 2020;131:411-448.

This consensus statement provides evidence-based guidelines for the management of PONV in the adult and pediatric populations. It discusses mechanisms of action as well as strength of data supporting available antiemetics.

Li T, Li J, Yuan L, et al. Effect of regional vs general anesthesia on incidence of postoperative delirium in older patients undergoing hip fracture surgery: the RAGA randomized trial. *JAMA.* 2022;327:50-58.

Although there may be other benefits to neuraxial anesthetic techniques, avoiding general anesthesia did not impact the rate of postoperative delirium in elderly patients undergoing hip fracture surgery.

Myles PS, Leslie K, Chan MT, et al. The safety of addition of nitrous oxide to general anaesthesia in at-risk patients having major non-cardiac surgery (ENIGMA-II): a randomised, single-blind trial. *Lancet.* 2014;384:1446-1454.

In contrast to previous trials, the Evaluation of Nitrous Oxide in the Gas Mixture for Anaesthesia (ENIGMA) II Trial reported that use of nitrous oxide was not associated with an increased incidence of death, cardiovascular complications, or wound infection in high-risk surgical patients. Although the incidence of severe postoperative nausea and vomiting (PONV) was higher (15% vs. 11%) in patients receiving nitrous oxide compared with controls, the occurrence of PONV in the nitrous oxide group was effectively controlled by antiemetic prophylaxis.

American Society of Anesthesiologists Task Force on Perioperative Management of Patients with Obstructive Sleep Apnea. Practice guidelines for the perioperative management of patients with obstructive sleep apnea: an updated report by the American Society of Anesthesiologists Task Force on Perioperative Management of Patients with Obstructive Sleep Apnea. *Anesthesiology*. 2014;120: 268-286.

Guidelines for the preoperative assessment, perioperative management, and postoperative disposition of patients with obstructive sleep apnea.

Radtke FM, Franck M, Lendner J, Krüger S, Wernecke KD, Spies CD. Monitoring depth of anaesthesia in a randomized trial decreases the rate of postoperative delirium but not postoperative cognitive dysfunction. *Br J Anaesth*. 2013;110:i98-i105.

Processed electroencephalogram can help guide anesthetic dosing in a manner that can potentially reduce risk for delirium postoperatively but cannot prevent postoperative cognitive dysfunction.

Santa Cruz Mercado LA, Liu R, Bharadwaj KM, et al. Association of intraoperative opioid administration with postoperative pain and opioid use. *JAMA Surg*. 2023;158:854-864.

Recent cohort study of >60,000 surgical patients that demonstrated an improvement in postoperative pain control and a decrease in chronic pain with higher intraoperative opioid administration. This makes a different argument in the current largely opioid-sparing culture.

Substance Use Patients
Implementation Considerations
Rehabilitation
Conclusions

BACKGROUND

As the field of medicine has advanced, the average surgical patient's age, comorbidities, medications, and body mass index (BMI) have all increased. As a result, surgeons are completing more challenging operations on more complex patients. It is established that preoperative multimorbidity is a strong prognostic indicator of postoperative function, morbidity, and mortality.[1] Additionally, in the last decade, the role of the surgeon and surgical practice has increased in the preoperative phase of care. Specifically, the focus on enhanced recovery after surgery (ERAS) pathways brought to light the importance of preoperative education and management of comorbidities. Most pathways include some elements of preoperative assessment and/or optimization as well as patient education. Ultimately, with the intent of proactive management of medical and functional status to ensure optimal surgical and patient-reported outcomes, the terms *prehabilitation* and *rehabilitation* have gained traction.

Prehabilitation and rehabilitation are multidimensional approaches that aim to take a holistic view of the surgical episode from the point the decision for surgery is made until the patient is back in their home environment. The preoperative period is a natural time to engage patients regarding healthy lifestyle choices because this time is generally paired with a newly diagnosed chronic illness or cancer. Therefore, the focus of prehabilitation is on engaging a patient in behavior modification for optimization, as opposed to the traditional preoperative practice of simply assessing and risk-stratifying patients. In contrast, rehabilitation focuses on restoring both physical and mental functional capacity as well as quality of life in the postoperative setting. Collectively, prehabilitation plus rehabilitation aims to deliver goal-concordant care and ensure that functional status is restored to the best level possible after major surgery. Some prehabilitation components even specifically target preparing for rehabilitation exercises the patient may participate in, such as the use of incentive spirometry or logrolling to sit up after major abdominal surgery. Studies on surgical patients have shown an additive and synergistic effect of prehabilitation when paired with rehabilitation on functional capacity, fitness, hospital length of stay, and complication rates.[2] Additionally, prehabilitation and rehabilitation interventions together can modify frailty, which can improve functional status and mitigate morbidity and mortality.[3,4]

PREHABILITATION

Although conceptually exciting, the evidence for prehabilitation is evolving. Broadly, studies discuss prehabilitation as the idea of training and prepping for surgery, giving patients a sense of control. Studies are largely heterogeneous and highly selective regarding patient populations, interventions, and outcome measures, which makes the results difficult to generalize to surgical patients at large and across diverse health systems outside of the controlled research setting. Another challenge with studies around prehabilitation has been measuring the impact on meaningful clinical outcomes. The evidence is mixed with regard to the role of prehabilitation in reducing traditional 30-day surgical complications, but it may be that the correct outcomes are not being assessed, and, instead, rehabilitation is aimed at improving patient-reported and functional outcomes after surgery and promoting the delivery of goal-concordant care—all outcomes that are far harder to measure than traditional 30-day surgical outcomes like surgical site infection and urinary tract infections but are likely far more meaningful to patients and their loved ones.

Prehabilitation protocols can be unimodal or multimodal, and the vast majority include one or more of the following interventions: nutrition, exercise, and/or mood. Studies suggest multimodal interventions are superior given the synergistic effects, and protocols incorporating exercise, diet, and psychological interventions can improve functional outcomes both before and after surgery.[5,6] Duration and timing of intervention are also debated, especially in the setting of resource-heavy interventions. However, Ploussard et al. suggested that even a single-day prehabilitation intervention before robotic radical prostatectomies can have positive results.[7] This study intervention was a one-day "PreHab" workshop, which included nutritional advice and exercise recommendations, and was paired with an ERAS protocol. They found that the ERAS + PreHab protocol worked synergistically to significantly shorten length of stay and lessen intraoperative blood loss and operative time. Additionally, ERAS + PreHab improved costs compared with ERAS alone, and it showed improvement by 22% when compared with no intervention.[7] At the other extreme of interventions, PREHAB, an international, multicenter, randomized controlled trial (RCT) showed that a supervised 4-week, in-hospital prehabilitation program that included high-intensity exercise three times per week, nutritional and psychological intervention, and all smoking cessation (if applicable) showed a reduction of severe complications by 50% in the prehabilitation group and improved postoperative functional capacity.[8]

Keeping the many limitations in mind, studies have shown positive outcomes with prehabilitation improving functional capacity and fitness, reduced hospital length of stay, lower complication rates, and cost savings.[2,9] Howard et al. found an average savings of $21,946 per patient and recommended prehabilitation consideration for all patients.[9] Trépanier et al. pooled data from three prehabilitation studies and found in the setting of stage III colorectal cancer that prehabilitation was associated with an improved 5-year survival.[10] Additionally, in the wake of the COVID-19 pandemic, patients faced delays in care, limited resources, and added COVID-19–related morbidities. Authors have argued prehabilitation protocols can help mitigate these additional burdens that COVID-19 has placed on both individual patients and the healthcare system[11] and use the delay in surgical timing for positive interventions.

Successful efforts to systematize the preoperative period and implement prehabilitation on a larger scale can be seen in the Peri Operative Programme Péri-Opératoire (POP) at McGill, Strong for Surgery by the American College of Surgeons (ACS), and Michigan Surgical & Health Optimization Program (MSHOP). In 2007 McGill University Health Centre initiated prehabilitation efforts, and in 2011 it incorporated a not-for-profit organization, POP, to continue their robust research efforts. Research from McGill has in many ways laid the foundation for our current working definition of prehabilitation with their most recent contribution of the PREHAB randomized clinical trial previously mentioned. Current research focuses on implementation barriers and suggests a paradigm shift in the preanesthesia care structure.

Strong for Surgery is a dedicated effort by the ACS to improve preoperative comprehensive screening and risk stratification and to guide necessary referrals. This initiative encourages providers and healthcare systems to implement routine screening checklists preoperatively. They include eight targeted areas, one of which is prehabilitation. Their prehabilitation protocol recommends screening all patients older than 65 for physical limitations and frailty, suggesting baseline assessments with grip strength or the Timed Up & Go test and possible referral to a geriatrician. They also recommend consideration of preoperative consultation with a cardiologist in the setting of unstable cardiac disease, pulmonology referral in the setting of unstable pulmonary disease, and physical therapy with a daily walking program composed of two to three walks per day in patient populations with poor mobility or diminished endurance.[12] The other areas of focus in Strong for Surgery are nutrition, glycemic control, medication management, smoking cessation, pain management, delirium, and patient directives,[13] which are all components critical for preoperative optimization whether they are included in a prehabilitation bundle or other preoperative optimization bundle or pathway.

MSHOP is a statewide comprehensive surgical preparation and training program that was developed at the University of Michigan. It shows effectiveness and generalizability of prehabilitation across diverse patient populations, hospital systems, and practices. They conducted a prospective multicenter cohort study across 21 Michigan hospitals assessing the impact of a prehabilitation program that included a home-based walking program with daily reminders and education on nutrition, smoking cessation, stress management, care planning, and incentive spirometry instruction.[14,15] Their program is an example of a scalable model of prehabilitation that decreases hospital length of stay and lowers total episode payments for Medicare beneficiaries. Their model is now standard practice for major inpatient general and thoracic surgery at the University of Michigan, and in a pilot setting, Blue Cross Blue Shield of Michigan has started a reimbursement process.

PREHABILITATION COMPONENTS

As hospital systems develop and deploy prehabilitation programs, they will inherently be variable and constructed to best fit each unique healthcare system and patient's needs. Some components may be tied into preexisting perioperative bundles or ERAS pathways. However, other prehabilitation programs will encompass all necessary preoperative patient optimization components. The evidence of the synergistic effects of multicomponent prehabilitation programs and prehabilitation programs + ERAS pathways suggests the following components should be considered for inclusion: nutrition, glycemic control, medication management, tobacco cessation, pain management, delirium prevention, exercise, and psychological optimization with a focus on anxiety and depression. Other important areas that can be considered preoperatively for optimization but are not discussed in this chapter specifically are anemia, weight loss, and completing patient directives.

Nutrition

Appropriate nutrition, especially in critically ill and malnourished patients, decreases rates of infection, hospital and intensive care unit (ICU) length of stay, and duration on the ventilator.[16] Therefore, nutritional optimization is a key area of focus in the elective surgery preoperative setting. It is key to assess nutrition multidimensionally. The ACS Nutrition Screening checklist is an example of what aspects can be important in screening for malnutrition. They recommend any patient who is not receiving established nutrition therapy to get a referral to a registered dietician if they have a BMI less than 19, over 8 pounds of unintentional weight loss in the past 3 months, a poor appetite as defined by eating less than half of their meals or fewer than two meals per day, or are unable to tolerate oral intake. They also recommend a routine serum albumin check if the patient is scheduled for an inpatient procedure and immune modulating supplementation if the patient is having "complex" surgery. However, it is important to note, and emphasized in the American Society for Parenteral and Enteral Nutrition (ASPEN) guidelines, that albumin and prealbumin should not be used in isolation for assessment of preoperative nutritional status because they are markers of inflammatory metabolism,[17] and using these laboratory values in isolation can over diagnose malnutrition. Nutrition is identified as a critical piece of optimization for surgery, and the vast majority of prehabilitation protocols incorporate a nutrition intervention.

Addressing nutrition proactively before surgery can assist in the body's ability to respond to the additional insult of surgery. Early optimization and focus on nutritional supplements, protein, complex carbohydrate intake, and proper hydration are key to prepping our patients for surgery and mitigating loss of muscle, strength, and functional capacity.[18–20] Specifically, providing nutritional guidance for patients undergoing gastrointestinal or cancer surgery is associated with improved morbidity.[21] Preoperative carbohydrate-loading nutrition drinks are a component of many preoperative pathways. A recent systematic review and network meta-analysis of phase II and III RCTs suggest that preoperative carbohydrate drinks are associated with shorter lengths of stay, improvements in insulin resistance and sensitivity, and improved C-reactive protein (CRP) values. However, carbohydrate drinks and water had equal improvements compared with fasting in regard to improvements in postoperative nausea and vomiting and overall lower morbidity.[22] Studies have also found that diet modification, especially through engagement with a dietician, can even significantly improve pain scores and quality of life in chronic pain patients, and referral to a dietician should be considered.[23–25]

Glycemic Control

Glycemic control in the perioperative period is paramount across all surgical patients, and focus on control should not be limited to the known diabetic population. Hyperglycemia is a well-established risk factor for increased rates of infection, poor wound healing, longer hospital length of stay, and increased mortality.[21,26] Despite the known negative impacts, studies show blood glucose levels greater than 140 mg/dL occur in up to 40% of general surgery patients and 90% of cardiac surgery patients.[26] In the prehospital setting providers can screen for risk factors predisposing patients to difficulty with perioperative glycemic control. One suggested way for the screening proposed is that all patients with a prior diagnosis of diabetes, age over 45, or BMI greater than 30 have their fasting blood sugar checked before entering the operating room. Hemoglobin A1c >7.0% or a fingerstick over 200 mg/dL in the prior 2 weeks warrants a referral for diabetes management.[27]

Medication Management

Obtaining an accurate medication history—including over-the-counter medications, herbal supplements, and doses—is essential in the preoperative setting. A particular focus should be placed on identifying polypharmacy and patients taking antiplatelets, anticoagulants, β-blockers, or steroids as well as those receiving immunotherapy. One should note indications and duration of use and contact the prescribing provider, if necessary, to discuss risks and benefits of holding the medication perioperatively. When safe, the ACS recommends holding anticoagulants, including Coumadin, Plavix, and others, for 1 week before surgery. Evidence is evolving, but aspirin used for preventative purposes only may be discontinued preoperatively. The American Heart Association (AHA) and American College of Cardiology (ACC) recommend that patients on chronic β-blockade undergoing noncardiac surgery should continue treatment through the perioperative period.[28] Medication management emphasizes the importance of comprehensive clinical care and multidisciplinary teams in the weeks leading up to surgery. Patients with an intermediate or high risk of myocardial ischemia or those with three or more Revised Cardiac Risk Index risk factors—such as diabetes, heart failure, coronary artery disease, renal insufficiency, or cerebrovascular accident—can be started on β-blockade preoperatively. However, the timing of initiation is critical, as is management with a multidisciplinary team.[28] According to the AHA/ACC guidelines for preoperative management of hypertension, medical management can continue up until the planned elective procedure, and the discontinuation of angiotensin-converting enzyme (ACE) and angiotensin receptor blockers (ARBs) is considered. Additionally, it is reasonable to reschedule elective surgery for systolic blood pressures 180 mm Hg or higher and diastolic blood pressures 110 mm Hg or higher.[28,29]

All over-the-counter medications and herbal supplements that may increase risks of bleeding, such as NSAIDS, echinacea, garlic, gingko, ginseng, kava, saw palmetto, St. John's wort, and valerian, should be held 2 weeks before surgery.[30] The American Geriatrics Society Beers Criteria (AGS Beers Criteria) for Potentially Inappropriate Medication (PIM) Use in Older Adults is an essential resource for clinicians in assessing safety of medications for the geriatric population.[31] It should be used in the preoperative setting to assess what medications should be held for surgery or, in collaboration with their primary care provider, discontinued altogether.

Tobacco Cessation

Encouraging tobacco cessation preoperatively is well established as routine practice. Many institutions have incorporated cessation as part of their preoperative pathways and ERAS protocols, with some surgical subspecialties mandating it preoperatively for elective surgery, even testing for nicotine levels given the known negative effects. For institutions that have not done this, it should be strongly considered as part of a prehabilitation protocol. Tobacco smokers are at significantly higher risk of infection, poor wound and bone healing, and impaired cardiopulmonary function in the postoperative setting compared with nonusers. A subset of negative effects including prolonged recovery and adverse respiratory outcomes extends to people exposed to secondhand smoke, especially children.[32] The World Health Organization completed a review of RCTs that showed interventions to support cessation significantly reduced the incidence of any postoperative complication, surgical site infections, and morbidity. Additional observational studies show an association between tobacco use and all complications, infections, neurologic and pulmonary complications, ICU admission, wound infection, delay in healing, dehiscence, and hernia occurrence.[21,32,33] All surgical patients benefit from smoking cessation; however, the gastrointestinal tract is particularly sensitive to the toxic effects of smoking, and patients undergoing bowel resection benefit from cessation to a greater extent than other patients.[32–34] The most profound benefits are consistently seen after 3 weeks of cessation, and some studies show that each week past 4 weeks of cessation confer 19% of additional reduction of morbidity. The best evidence is for behavioral interventions with weekly check-ins, nicotine replacement therapy, and cessation programs.[32] Support in the preoperative period should be as early as possible to maximize these potential benefits, which would support early initiation of prehabilitation protocols.

Pain Management

Multimodal pain control should be considered as part of prehabilitation protocols if not already incorporated into the established care model through ERAS pathways. Up-front conversations about pain medications to set expectations and discuss strategies for safe multimodal pain control after surgery can be helpful. Additionally, referral to a pain service for patients with a 3-month or longer history of opioid use before surgery is recommended.[35] To reduce opiate use postoperatively, it is important to integrate multimodal, nonopioid agents and pain management strategies throughout the entire perioperative and operative experience.[36] Preoperative physical activity, nutrition optimization, and engagement with online platforms aiding in opioid cessation can significantly reduce postoperative opioid use and expedite opioid cessation.[24,37]

Delirium Prevention

Postoperative delirium is the rapid onset of confusion. Causes of delirium can be multifactorial. It is a problem that disproportionately affects the elderly population and up to 50% of patients undergoing high-risk procedures.[38] Delirium can be either hypoactive or hyperactive and can last days to weeks, with some patients never appearing to fully recover. Furthermore, it is associated with cognitive and functional decline, loss of autonomy, longer hospitalization, more ICU admissions, greater healthcare costs, and higher rates of mortality.[38,39] The ACS recommends screening for risk factors for delirium in the preoperative setting assessing patients over 65 years old and those with cognitive deficits, poor functional status or a history of falls, and underlying severe illnesses or infection; vision or hearing loss should also be noted. If the patient meets any of these criteria, consideration of further evaluation is necessary. Optimization to prevent delirium includes removing medications that are associated with delirium; performing sleep hygiene preoperatively; ensuring assist devices such as hearing aids, dentures, and glasses are packed for the hospital and used while an inpatient; including sign-up sheets for family and friends at bedside; checking orientation frequently; and providing large-faced clocks and visible dates in the room. It is also important to screen for metabolic and electrolyte abnormalities as well as delirium-causing medications preoperatively with enough time for safe correction and cessation. Some current study protocols are focused on the possible effects of home-based exercises, dietary management, and iron infusions on postoperative delirium.[38]

Exercise

Exercise is a critical aspect of prehabilitation protocols and has been found to significantly reduce postoperative pulmonary complications, overall morbidity, disability, and pain.[40–44] A systematic review of studies examining exercise prehabilitation in patients undergoing bowel resection found it significantly improves postoperative functional capacity.[45] Minnella et al. completed a single-center single-blinded RCT that evaluated high-intensity interval training (HIIT) versus moderate-intensity continuous training (MICT) and determined that both improved preoperative functional capacity without a significant difference between the two.[46] This suggests room for customization of prehabilitation protocols allowing for specific interventions to fit what patients will engage with most. Programs can be further individualized to meet specific populations' needs, with tailored programs for orthopedic patients versus vascular patients or programs focused on specific body parts such as the operative limb. Other studies have shown significant reduction in postoperative complications in patients who engage in community-based exercise programs or when patients are provided educational pamphlets on exercise interventions.[47,48] The significant results across exercise interventions suggest that engagement in exercise preoperatively is essential.

Psychological Health: Anxiety and Depression

Surgery is a stress to every system in the body that requires both physical and psychological reserve. Studies have shown that anxiety negatively effects outcomes and impacts length of stay, immune function, ability to heal wounds, and return to function. Additionally, it impacts patient engagement and motivation.[21] It is estimated that 50% or more of patients experience perioperative anxiety. Perioperative anxiety is associated with increased anesthetic use, which can negatively impact recovery and increase rates of nausea, emesis, and cardiopulmonary symptoms.[49] Wada et al. found that anxiety in cancer patients is a strong predictor of postoperative delirium, and Ramirez et al. found an association between depression and nonhome discharges postoperatively.[50,51] Understanding our patients' propensity for anxiety and depression in the perioperative period and improving coping mechanisms through standardized preoperative prehabilitation pathways can improve surgical outcomes. Numerous methods for stress reduction and anxiety mitigation strategies have proven effective ranging from music, meditation, guided imagery, acupuncture, cognitive behavioral therapy, and others,[52] which allows for customization to hospital resources and/or patients.

AT-RISK POPULATIONS

As discussed previously, there is no standardized time frame for prehabilitation interventions, and groups studied are heterogeneous, which makes it difficult to generalize recommendations. In an era of limited resources, it can be argued that efforts should be focused on the most at-risk populations initially. The most notable populations that targeted efforts could support are frail patients with preexisting limited physical reserve, surgical oncology patients, and other at-risk populations such as substance use disorder patients.

FRAIL PATIENTS/DECREASED PHYSICAL RESERVE

First and foremost, understanding our patients' goals in the setting of elective surgery is critical. Zattoni et al. noted that frailty is the most important prognostic factor for postoperative complications, increased length of stay, and functional and cognitive decline.[53] Frailty is also associated with increased mortality, regardless of the operative stress of the procedure,[54] morbidity, and cost.[55] Functional preservation is paramount, especially in the geriatric population where functional loss is quite difficult to regain and is often "more feared than death."[53] McLennan et al. found that patients unable to climb two flights of stairs were over four times more likely to have a postoperative complication and prolonged length of stay.[56] Poor preoperative functional status is also correlated to nonhome discharges,[57] and improved functional capacity is associated with fewer severe postoperative complications.[5] Frailty is a modifiable risk factor. Functional performance can improve with prehabilitation and rehabilitation, which can mitigate morbidity and mortality.[3,4] McIsaac and colleagues are currently completing the PREPARE trial, a multicenter RCT on a frailty-specific prehabilitation protocol that focuses on postoperative complications and disability as outcomes.[58] Healthcare providers can capitalize on frailty as a predictor of postoperative outcomes, act to improve preoperative functional status through prehabilitation measures, and work to streamline discharges for patients seeking preapproval for acute rehabilitation and care facilities. In contrast, Carli et al. completed a randomized clinical trial that assessed 30-day postoperative complications for frail patients after prehabilitation and colorectal resection, which showed no improvement in outcomes compared with rehabilitation.[59] This supports the need for continued research to assess best optimization for this population because they may benefit most from the synergistic effects of prehabilitation plus rehabilitation or evaluation at later end points such as 90 days.

SURGICAL ONCOLOGY PATIENTS

Prehabilitation in surgical oncology patients has been found to have positive effects on postoperative functional status, maintenance of lean muscle mass, shortened hospital stay, improved complication rates, and quality of life. Recent studies support that improving nutrition, functional capacity, and psychology in the time of neoadjuvant treatment for surgical oncology patients can further bolster these results.[2,60] Although delaying surgery for prehabilitation alone, particularly in cancer patients, is debated, the expanding role of neoadjuvant therapy across diseases could offer a built-in time for prehabilitation protocols to be implemented.[42] There is evidence for the use of both unimodal and multimodal prehabilitation protocols in cancer patients, with additional unique findings in oncologic subpopulations such as reduced number of days requiring chest tubes in thoracic postoperative patients who engage in prehabilitation protocols.[61] Multiphasic prehabilitation has also been suggested for cancer patients where prehabilitation is assessed for and implemented multiple times preoperatively through the course of neoadjuvant therapy.[2]

SUBSTANCE USE PATIENTS

The risks of smoking are well established and discussed previously in this chapter. Alcohol use disorder is also linked with worse surgical outcomes.[62] Over two alcoholic drinks per day is associated with increased postoperative infections, pulmonary complications, greater length of stay, and increased need for ICU care. Fernandez et al. noted additive negative effects when alcohol and smoking are combined preoperatively, and they found when the substances are used in conjunction, there are significant synergistic deleterious effects resulting in increased complications, readmissions, and reoperations.[62] Tang et al. found higher levels of opioid use in the preoperative phase was associated with higher rates of readmission,[63] highlighting the need for preoperative substance use screening and strategies for intervention for substances known to affect health and surgical outcomes. These unique considerations and complications for this population suggest that they could benefit from screening, intervention, and additional support preoperatively. A systematic review and meta-analysis of preoperative interventions for alcohol and other recreational substance use found that preoperative interventions can reduce substance use, but interventions do not reduce hospital length of stay, morbidity, or mortality.[64] Future studies could assess whether incorporation into a comprehensive prehabilitation protocol can be impactful.

IMPLEMENTATION CONSIDERATIONS

As with any novel intervention, models for achieving optimal perioperative care will vary based on existing resources and system structure. One solution trialed at the University of California San Francisco lead by Dr. Finlayson focused efforts on the at-risk geriatric population by establishing a Geriatric Optimization Clinic. Finlayson et al. found that although the prehabilitation clinic was valuable, it was challenging to support the specialists' time to participate (nutrition, physical therapy, geriatrics, and anesthesia), and, ultimately, the clinic was closed.[65] Carli et al. suggested integrating prehabilitation into the perioperative clinic but with a paradigm shift, noting the importance of moving the intervention forward in time to enable a longer intervention period because presently traditional preanesthesia clinic visits are quite close to the time of surgery.[66,67] The cost of providing care may be partially recaptured through the clinic billing as a preoperative visit rather than the primary care provider. Cost savings in the setting of prehabilitation would be realized by the system through decreased length of stay, fewer complications, and fewer readmissions. These improvements have reputational impact by increasing referrals and improving payer compensation. MSHOP shows promise for this cost savings and the potential for insurance reimbursement.

It is possible that as payment reform is pursued in the United States, incentives will shift, and it will "make sense" financially for providers and health systems to support more robust prehabilitation programs. One example is the Centers for Medicare and Medicaid Services Bundled Payments for Care Improvement initiative. In this program, hospitals are incentivized to ensure optimal outcomes because they are paid a set amount of money per episode (usually 90 days of care, initiated by a surgical encounter), and in the event the total cost of care is lower than the payment, they share in the savings; if total cost of care exceeds the payment, they incur financial penalty. Therefore, if indeed prehabilitation can improve postoperative outcomes and reduce costs for the episode, hospitals will engage. The model is imperfect, and uptake has largely been optional, but it is anticipated that other models will be released in the next few years. This will likely continue to push the adoption of prehabilitation and rehabilitation.

REHABILITATION

Before the conception and implementation of prehabilitation, perioperative care was mainly focused on postoperative rehabilitation. Rehabilitation after surgery is most developed in the fields of orthopedic and cardiothoracic surgery and has been shown to decrease pulmonary complications, length of stay, and hospital costs.[68] Multifaceted and multidisciplinary rehabilitation programs focusing on nutrition, strength, balance, and cardiorespiratory fitness have also proven efficacious in improving outcomes in thoracic and abdominal surgery populations.[65] Rehabilitation targeted at specific patient population needs has also proven to be efficacious. Postoperative exercise programs including those studied in the PROSPER trial resulted in reduced upper limb disability after breast cancer surgery,[69] and pulmonary rehabilitation after lung resection was found to significantly impact postoperative exercise tolerance.[70]

Efficacy of rehabilitation has been proven in a variety of settings including outpatient and inpatient physiotherapy, rehabilitation centers, clinics, and at home.[68] In critically ill patients receiving ICU-level care, early inpatient rehabilitation while in the ICU setting is associated with less ICU-acquired weakness.[71] Most recently there is a trend of assessing efficacy and satisfaction with rehabilitation via online platforms including phone-based applications, telerehabilitation, Xbox 360, and using artificial intelligence.[72–77] Some studies show equivalent or even better rehabilitation results using augmented reality compared with standard rehabilitation.[74–76] Application-based rehabilitation allows patients the flexibility to train at home,[72] and smartphone app–based postoperative monitoring has been shown to have improved quality of recovery and satisfaction compared with in-person follow-up.[78,79] Given the importance of rehabilitation, continuing to explore novel modalities to engage in rehabilitation and improve patient participation and satisfaction is essential.

CONCLUSIONS

Optimizing surgical outcomes requires multifaceted and multidisciplinary approaches that span the entire perioperative period. The preoperative phase is an opportunity for the provider and the patient to work together to take control of the patient's health and capitalize on a teachable moment in which healthy habits are established, maintained, and improved upon. Postoperatively, multifaceted rehabilitation strategies can lead to improved surgical outcomes. The perioperative time is an opportunity for preventative care bundles that standardize approaches to patient care and help facilitate comprehensive assessment and treatment. Care maps can help coordinate prehabilitation and rehabilitation and streamline care across clinical sites. Routine screening in these pathways can identify at-risk populations that require additional tailored care, whereas others may progress seamlessly through standardized prehabilitation and rehabilitation protocols.

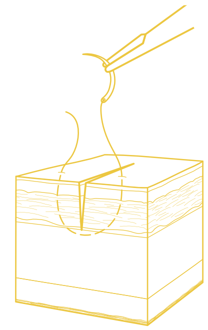
22 CHAPTER



Enhanced Recovery After Surgery (ERAS): Evidence-Based Perioperative Pathways to Optimize Outcomes

Olle Ljungqvist, Hans D. de Boer, and Gregg Nelson

OUTLINE

Introduction
- History of Enhanced Recovery After Surgery
- What Makes Enhanced Recovery After Surgery Work?

Enhanced Recovery After Surgery Society Guidelines

Enhanced Recovery After Surgery Components
- Preadmission Optimization and Prehabilitation
- Preoperative Care Elements
- Intraoperative Care Elements
- Postoperative Care Elements
- Early Mobilization
- Discharge and Follow-Up

Enhanced Recovery After Surgery Implementation Program
- Audit
- Enhanced Recovery After Surgery Team

Enhanced Recovery After Surgery Outcomes
- Roles and benefits for Enhanced Recovery After Surgery practitioners

Conclusion

INTRODUCTION

Enhanced Recovery After Surgery (ERAS) is a program for perioperative care based on the best available evidence in medical literature. Employing the principles of ERAS has revolutionized surgery and surgical care and has yielded marked improvements in outcomes for patients reducing recovery time and suffering from complications, while freeing up hospital resources and reducing cost. In this chapter all important aspects of ERAS will be presented.

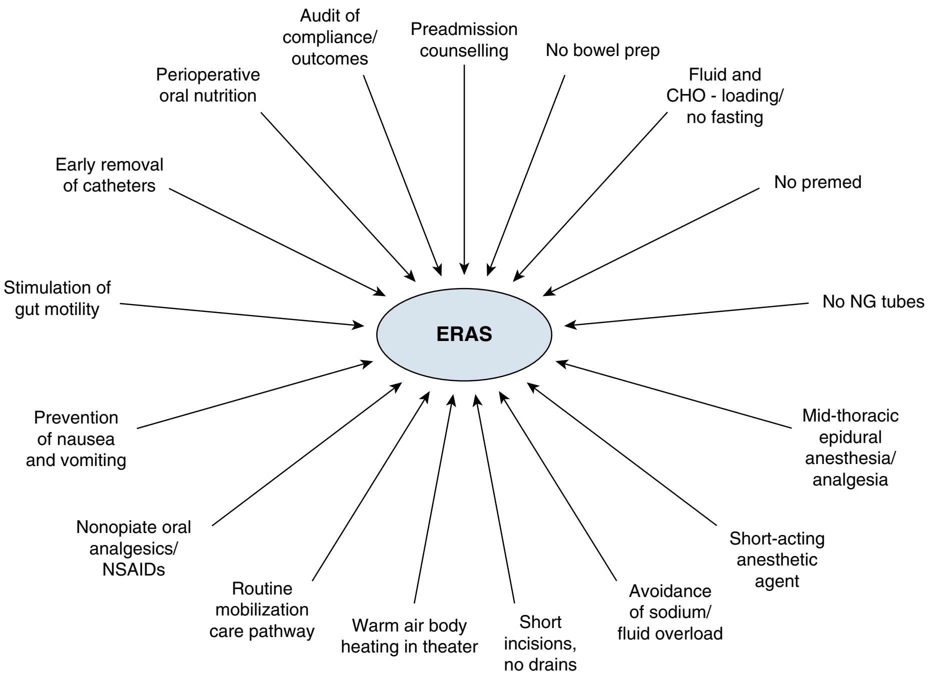
History of Enhanced Recovery After Surgery

To understand why and how ERAS has become what it is today, it is important to understand how it developed over the past decades. In more recent times, the idea of bundling care elements to a care protocol was first presented by Engelman and coworkers for cardiac surgery patients.[1] They reported case series employing a care bundle consisting of fluid management and pain control and showed that they could "Fast Track" patients through recovery in the intensive care unit (ICU) and in the hospital with this program. Shortly thereafter Henrik Kehlet, a surgeon from Denmark, reported that his Fast Track program combined with laparoscopic surgery in eight elderly patients (ages 71–88 years old) undergoing segmental colonic resections resulted in recovery and discharge from the hospital 2 days after the operation.[2] This was a sensation at the time when length of stay for the average patient was 2 weeks for this type of operation. He later expanded his thoughts in a review paper in which he described his ideas of a multimodal approach to recovery after major surgery. The key elements included were preoperative information, attenuation of stress, pain relief, exercise, enteral nutrition, and growth factors. In a larger case series of colonic resections, now performed with open surgery, he confirmed his earlier results by having more than half the patients discharged 2 days after surgery.[3]

These results inspired Ken Fearon (United Kingdom) and Olle Ljungqvist (Sweden) to gather a group of surgeons to form a group to study this remarkable approach further. Joined by Arthur Revhaug (Norway), Martin von Meyenfeldt (Netherlands), Cornelius DeJong (Netherlands), and Henrik Kehlet (Denmark), they initiated the Enhanced Recovery After Surgery Group in 2001.[4] It was felt that rather than aiming for *fast,* the target should be *recovery,* and that was the birth of "ERAS."

Building on the principles of a multimodal approach, but not selecting just a few care elements, the group set off to search for all elements of care that had data in support of enhancing recovery to form a care protocol. Involving younger colleagues from all units, the team scanned the literature and published the first ever evidence-based guide for perioperative care in colonic resection in 2005.[5] The elements included are shown in Fig. 22.1 and included additional items on top of the ones proposed by Kehlet.

During this early period the group made several key discoveries that helped form ERAS. Having built the first ERAS protocol, the members realized that none of them were employing all elements they had found in the literature. Second, they also saw that they had different missing items; thus, the care delivered was very different between units. They set out to change practices to align with the newly produced guideline and see if this would improve their outcomes. Before embarking on this, clinical teams had length of stay at the upper end of what was average at the time, and hence, far from the 2 days that Kehlet's group had presented. The group



Audit of compliance/ outcomes
Preadmission counselling
No bowel prep
Fluid and CHO - loading/ no fasting
Perioperative oral nutrition
Early removal of catheters
No premed
Stimulation of gut motility
ERAS
No NG tubes
Prevention of nausea and vomiting
Mid-thoracic epidural anesthesia/ analgesia
Nonopiate oral analgesics/ NSAIDs
Short-acting anesthetic agent
Routine mobilization care pathway
Warm air body heating in theater
Short incisions, no drains
Avoidance of sodium/ fluid overload

FIGURE 22.1 Main elements of the initial Enhanced Recovery After Surgery *(ERAS)* Consensus protocol. *CHO,* Carbohydrate; *NG,* nasogastric. (From Fearon KC, Ljungqvist O, Von Meyenfeldt M, et al. Enhanced recovery after surgery: a consensus review of clinical care for patients undergoing colonic resection. *Clin Nutr.* 2005;24[3]:466-477.)

also started to include rectal surgery to widen the scope. When setting off this project, a database was formed to capture all relevant data that could affect outcomes, including demographics, key comorbidities, all care items of the ERAS protocol, key surgical and anesthesia elements, and outcomes. All items in the database were thoroughly defined. Once reviewing the data after having collected several hundred patients, two important discoveries were made. All units found that they were wrong about their own practice. The review performed for compliance to the ERAS protocol done before the audit was very different from what the real-life data revealed. Problems existed where things were believed to be running well and vice versa. All units found elements of care that needed to be put in place, and several of them were completely unexpected by the teams. It was obvious that the only way to be able to test the guideline and its use was to continuously audit all processes and feedback continuously to those responsible for the care on the surgical floor to ensure that all elements of care were being used. Without this audit, focus would have been directed the wrong way and the important changes needed never addressed.

The group also found that the protocol was not going be sufficient to implement ERAS, a structural change in how the work was led and run was also needed (Fig. 22.2).[6] Audit is one key, but building the team to run the audit and lead the changes and ERAS on the floor was another key to success. The team had to employ representatives of all professions and disciplines involved in the care of the patient, and every station the patient passes during the care journey needs to be represented. The team needs to work in parallel and together and make sure that every ERAS care element is delivered at the right time to make the entire journey flow at its best.

These ideas were further tested in the Netherlands where Dutch colleagues teamed up with the Dutch Institute for Healthcare Improvement. They employed a structured method for implementation of the ERAS protocol and could train more than 30 hospitals in ERAS across the Netherlands. In less than a year, length of stay averaged a 30% to 50% reduction, which showed it was possible to make marked improvements with this care in a short time.[7]

Around the same time two important studies were published that caused the interest in ERAS to boom. Dileep Lobo and the ERAS group reported that not only was length of stay reduced with ERAS, but complications were markedly reduced.[8] This was a breakthrough later confirmed many times over. Gustafsson et al. showed a clear relationship between better compliance to the elements of the care pathway for open colorectal cancer surgery and reduced complications.[9] A 5-year follow-up study reported that with higher ERAS compliance and fewer complications, survival was improved.[10]

With the insights of knowing that (1) the literature could help lead the way to better care when all elements were assembled in an evidence-based fashion, (2) structured implementation required a multidisciplinary multiprofessional ERAS team, and (3) continuous audit that captured care processes and outcomes together was needed, the ERAS Study group decided to start a nonprofit medical society. The first nonprofit enhanced recovery society was formed and named the ERAS® Society (www.erassociety.org) in 2010[4] with the mission to develop perioperative care and to improve recovery through education, research, audit, and implementation of evidence-based practice.

To be able to support the implementation with an information technology (IT) system and administration of the implementation program, the group decided that a for-profit company should be started to be contracted to the Society. This partnership has run the implementation of ERAS in more than 30 countries worldwide, where all the knowledge and medical content come from the ERAS® Society network supported by the IT systems harboring the guidelines. In this endeavor, the ERAS® Society has developed a network of hospitals around the world that work together to help units to implement ERAS (Fig. 22.3).[11] In many of these

countries, national or regional ERAS Societies have been established, all connected to the main Society (see www.erassociety.org for details and updates). In Latin America, there is a joint Society ERAS LatAm, and countries in North America, Europe, and Asia have national societies such as ERAS USA, ERAS UK, and the newly formed ERAS Japan to mention a few. In addition to these regional and national ERAS Societies, there are also some specialty societies formed and connected to the ERAS Society, including ERAS Cardiac and ERAS Gynecologic Surgery. The same methodology has been used throughout the world for ERAS implementation, and units collect data on the same audit system. This allows for joint research to be performed in a unique way. Several research papers have been published based on data collected jointly in the ERAS® Interactive Audit System, several of them as national and international multicentric efforts.

What Makes Enhanced Recovery After Surgery Work?

Stress Reactions to Surgery

The body reacts very quickly to any type of injury, including surgery.[12] The degree to which these reactions occur are related to the extent of the injury and which body part is affected. The human body reacts to tissue injury via afferent nociceptive pathways to activate the hypothalamus, the sympathetic nervous system, the endocrine systems (in particular the adrenals and the pancreas), and, finally, by also activating the immune system (Fig. 22.4). This stress reaction sets off a rapid release of several stress hormones including catecholamines, cortisol, glucagon, and growth hormone. In parallel, the immune systems react by releasing cytokines creating a state of inflammation. These reactions together cause an almost immediate change in body metabolism leading to a state of catabolism.

Liver glycogen is mobilized to release glucose. This is further augmented by gluconeogenesis where the building blocks come from muscle glycogen, fat depots where lipolysis is initiated, and amino acids from protein breakdown occurring in muscle. At the same time glucose uptake is hampered in muscle because of the resistance to insulin caused by the release of stress hormones. This net effect is a marked rise in glucose levels. Acute phase proteins are synthesized in the liver from amino acids released from muscle. Body temperature rises, and hypermetabolism sets in.

Central in this change is the development of insulin resistance, a pseudodiabetic state of metabolism that develops to some degree in all patients after major surgery. The purpose of these reactions is to manage the injury, protect the body from further harm, allow mobilization of energy for “fight or flight,” and to prepare for a healing process. However, when exaggerated, these reactions can also cause harm. As a result of the stress

reactions, several metabolic changes are observed that relate to unwanted effects (Fig. 22.5).[13] High glucose levels after surgery have been associated with infections and a range of common postoperative complications.[14] In addition, the loss of glucose availability in the muscle for energy combined with a rapid loss of muscle tissue due to protein degradation have a major impact on muscle function with loss of strength and fatigue. This will affect all muscles in the body and can impact functions such as breathing and mobilization.

The Physiology of the Effects of Enhanced Recovery After Surgery

With the previous brief overview of the key stress responses in surgery as a background, it is interesting to find that many care elements reported in the literature to support recovery have stress-reducing effects. Some other care elements help maintain normal homeostasis. This suggests that a main mechanism by which ERAS delivers its effects is through reducing the body's responses to a given surgical stress.

A way to summarize the stress response schematically is to use the development of insulin resistance to grossly capture the body's reaction to surgery[15] (Fig. 22.6). Combining several elements of care (in this case for open surgery), the degree of stress that traditional perioperative care delivers can be compared with the care given according to ERAS. When several of the traditional elements of care (or lack of the right care) are added to one another, it becomes evident that the body reacts with less overall stress when using the ERAS pathway. In essence, with ERAS, the stress response elicited by a large surgery results in a reaction in the patient as if a much smaller surgery had been performed. This may explain why the patient feels less affected and recovers quicker and with fewer complications. One study reported almost no insulin resistance developing in patients undergoing major open colorectal surgery when employing a combination of epidural anesthesia that minimizes catecholamine and cortisol release, preoperative carbohydrate loading boosting insulin sensitivity before surgery, and early enteral feeding.[16]

In addition to the metabolic reactions described earlier, many of the elements of ERAS help maintain normal homeostasis. In traditional surgery and anesthesia, patients are often given high volumes of fluids during and after surgery to control blood pressure. This often rendered a weight gain of 4 to 6 kg or more of excess water.[17] This extra water remains in the body primarily harbored in cells such as the gastrointestinal tracts, subcutaneous tissues, and dependent areas of the body. Because the body strives to retain water after injury as another basic stress response, overload of fluid can last for days. During this time the excess fluid may contribute to several unwanted postoperative complications, including nausea, vomiting, and ileus because of fluid in the gastrointestinal tract. There may also be distention and pain from the wound because of swelling in the subcutaneous space. This can also lead to respiratory problems. Because overload of fluid causes several common complications,[18] balancing the fluids is another ERAS care item by keeping body water within reasonable limits and usually keeping weight gain within 2 kg.[19]

Yet another important ERAS care item is maintenance of body temperature. Avoiding drops of body temperature below 36.5°C (97.7°F) is associated with better outcomes. Cooler body temperatures have been associated with a range of complications including infection.[19,20]
